THE BIOLOGICAL CAUSE OF METABOLISM AND METABOLIC DISEASES.*

EFFORT SYNDROME—CAUSE AND TREATMENT OF FATIGUE, ARTHRITIS, NEURITIS, ARTERIAL SCLEROSIS AND OTHER METABOLIC DISORDERS.

BY FENTON B. TURCK, M.D.,

NEW YORK.

THE most extraordinary biological discovery within the last twenty-five years of research work, is that cell multiplication and metabolism is specifically excited by tissue extract. Another development of this fundamental biological principle, is that when these tissue extracts were liberated in excess of the biological requirements, disease and death were the inevitable result. So far our experiments show that the phenomena of life, health and disease, are based on these two fundamental laws. Whether this active cellular body was liberated from the cell by chemical, mechanical, or physical methods, the tissue extract always produced the same biological phenomena.

The writer demonstrated in 1896 that the liberation of this specific cell body was accomplished by fractional coagulation and filtration of the tissue substance through a Pasteur filter, and later by incineration to an ash. The "active principle" liberated, was found to act the same by whatever means were used in the extraction. The action in the organism only differed with the degree of concentration of the "tissue extract" when injected into animals or liberated in the tissues. It was found that mustard oil when introduced into the stomach, liberated from the tissue cells *in situ* this specific cellular substance always caused increased mytosis and metabolism. The metabolic activity of the cells was also increased by the liberation of tissue extract by use of nitrate of silver, weak solutions of chromic acid, tannic acid, and many other chemical agents. Especially was the reaction of increased mytosis noted when those tissues were involved that arise from the endodermic layer in the embryo such as the stomach.

The stomach and duodenum were the favorite sites of my earlier studies because of the prompt reaction that always occurs in the splanchnic zone, and I could readily remove from the gastric mucosa, material for examination from time to time by a simple instrument I invented in 1893 called the "gyromele." Material from the duodenum was also taken in the same manner as from the stomach, by passing the gyromele tube through the stomach into the duodenum (1894). Also specimens were taken from the deeper tissues by "nippers" and these fragments of tissue were fixed for histological study. When these tissue extracts were injected into animals, it resulted in violent reaction which occurred primarily in the splanchnic area and caused death. In the acute abrupt reaction, I called the phenomena "toxic shock" and because of the substance which produced the reaction "shock by toxin" (1894).

Many years ago I pointed out that the inner cylinder in the embryo, formed from the endodermic layer, was more responsive or sensitive than the outer cylinder which accounted for the reactions occurring always in the splanchnic area—the upper alimentary tract, including the embryological offshoots, the liver and lungs. These cells are the chief cells involved in all the biological reactions. It is this fundamental embryological factor that shows by vital statistics, the mortality of man.

Cytost and Anticytost in Metabolism.—To separate the metabolism of the cell from cell division and growth, is practically impossible. That which excites cell division must also include the taking up of pabulum and oxygen from the surrounding media or reserve supply and the liberation of energy. Every cell whether it be a complete organism, as the protozoa, or whether it be one of the coordinated multitude constituting the multi-cellular animals, has the power of growth through cell division.

In studying the life of the cell in the attempt to discover what is the activator of cell metabolism and division, we find (1) that injury of the cell, whether by *x*-ray penetration of the nuclear substance, or by penetration of the membrane by ice crystals, or by stirring up the protoplasm, results in a great outburst of chemical activity, literally an explosion of the disarranged components of the cell with resultant destruction of the cell. We find (2) that less violent stimulation, mechanical, physical or chemical, applied to the cell will liberate a loosely combined substance within the cell which sets the cell particles in motion and excites the cell to metabolism and division. This activating substance which can be isolated is found in the protozoa, in cell cultures of the higher animals, and in vegetable organisms. It can be easily extracted from any living or dead tissue of plant or animal by means of water, alcohol, or other agents, and by incineration which causes no loss of its specific effect. In laboratory experiments to distinguish this element which thus initiates cell

*Presented with demonstrations before the Academy of Medicine, Section on Nervous Diseases, Oct. 12, 1920, and in Symposium on Metabolic Diseases, Meeting of Medical Union, Cornell Club, April 26, 1921.

division and metabolism, we have named it *Cytost* (Cytos—a cell). The element which causes division and metabolism of the cell I have named *Cytost*.

Laboratory experiments further explain our findings. Tissue cultures supplied with uncoagulated blood plasma and placed in the incubator will not of themselves take up the pabulum from the blood and oxygen, and consequently will not grow. The addition of more blood, or stimulation by electricity or by acids or alkalies, or application of a greater degree of heat, all have perfectly negative results. The cultures still refuse nourishment. But the addition of a fraction of a drop of cytost (or rather of cytost in physiological proportions for the culture) immediately starts metabolism and cell division. Thus, in 34 tissue cultures, there were 384 transplants; in 308 of the transplants, homologous cytost was added to the cultures with the result that they continued to thrive; whereas, the other 76 transplants without the addition of cytost perished from lack of the required cell activation. Thus we may say that tissue cultures refuse to grow and metabolize until the extract of the cell is brought into contact with the living.

Cell Injection of Tissue.—Both young and adult animal metabolism is dependent upon this activator (cytost) and plant life requires the same stimulation.

Cytost is specific to the species; it must be extracted from animal cells of the same species as that of the tissue culture cells. Thus cytost from the cat will not activate dog tissue cells, nor will dog cytost affect human tissue; each tissue responds only to the tissue extract cytost) extracted from cells of its own species.

Injections of Varying Concentrations of Cytost.—As has been seen, the addition of physiologically suitable amounts of cytost to a tissue culture results in starting the cell particles to greater activity. When, on the contrary, a large amount of cytost (high concentration) is supplied in excess of the physiologic needs of the cell, the cell abruptly becomes viscous, the action of the particles is stopped, and the cell is dead. If a large but sublethal quantity of cytost is added to the cultures, cell activity is slackened, with eventual death from asphyxia and starvation. Similarly, injection of too high a concentration of cytost directly into the living intact animal (as dogs or cats) will bring about stasis and death. (Shock.)

The effect of cytost on the protozoa and on tissue cultures, the local tissue reaction in the living animal, and in the general organism of plants and animals as a whole, are expressions of the same law, *e.g.*, that a low concentration of cytost excites cell division and metabolism; that a higher concentration overexcites the viscosity reaction and slows the living activity; while a still higher concentration brings about such a high degree of viscosity that adsorption and death (shock) follow.

Anticytost.—The varying degree of cell reaction that follows the introduction of cytost indicates that an opposite element is present in cells to stabilize and preserve a delicate biological balance. This force resistant to cytost, its antibody, we call "anticytost." It is found normally in all blood and is created by the stimulating effect of small quantities of cytost that is liberated from the cells of the body. Our experiments have revealed that the degree of "anticytost" production in an animal is dependent on the graduated increased concentration of cytost introduced into the animal at regular stated intervals. These periodic injections render the animals relatively immune to the viscosity reaction of the higher concentrations of cytost. Hence, as in such adult vigorous animals, the plasma contains an excess formation of "anticytost," cells planted in plasma from these animals cannot metabolize and divide, owing to the inhibitory effect of the "anticytost" present. This inhibitory effect may be overcome and these same cells made to grow if an ordinarily lethal quantity of cytost be added to the blood plasma overcharged with "anticytost." Conversely, when a normal tissue culture begins to die from the viscosity reaction of an excess concentration of cytost, this reaction may be checked by the addition of "anticytost" and the culture saved. These facts prove that there is an exact balance between these two opposing substances. Likewise in the test tube, a combination of a lethal concentration of cytost with anticytost of the same species will neutralize the effect of the cytost so that no effect will be produced by the mixture (cytost-anticytost) either in tissue cultures or in injected animals. In other words, animals rendered actively immune to large or high concentrations of cytost showed in their blood serum a correspondingly high titre of antibody content which conferred immunity (passive) to other animals on injecting this immunizing antitoxin serum.

The blood of any animal may be so impregnated with anticytost (through the periodic injections of small doses of cytost) that the animal may be made so immune that he can withstand 500 times the dose of cytost that will kill a normal animal in three seconds. Thus we may understand why an old vigorous animal, made vigorous by repeated exercise, breaking down cytost, will have produced in his system more anticytost than a young weak animal. This explains why plasma from older, more vigorous animals prevent young tissue cells from growing, and why young and delicate animals must be used for obtaining the blood plasma for cultivating living tissues in vitro.

The ability to recover both of these cellular elements, cytost and anticytost, makes it possible to prove in vitro and in vivo that cytost is the only positively exciting agent that causes cell division and that its action is controlled by the negative agent, anticytost. These facts indicate that any agents whatsoever that result in cell division and metabolism must do so by first liberating cytost from the cell or within the cell.

Our ability to measure quantitatively as well as determine qualitatively the interaction of cytost and anticytost in the phenomenon of cell division and metabolism is as striking as the instantaneous death produced by cytost and the prevention of death by the administration of anticytost, or the combination of cytost and anticytost to form a neutral mixture. Between the two extremes of death and of increased normal metabolism are produced all the myriad biological expressions that are classified under the names of various pathological conditions. These facts are of such great scientific and practical application, as all our experiments have shown, that

we must conclude that we have here within our grasp a firm fundamental principle of wide application in biology. The application of this principle to the special field of therapeutics is only one phase of its general significance.

Investigations of this kind, to gain a measured knowledge of the subject, cannot be fruitfully carried out in the higher animals alone, but must depend also on the cultures of protozoa and cell cultures of higher forms, combined with physical and biochemical research. By these methods of research are furnished the most varied and conclusive evidence that bring us to the focal point of the determining factor in cell division and metabolism, in both healthy and diseased states of plant and animal life.

Liberation of Cytost in the Organism.—A. By a Deficiency Diet: Starvation and partial starvation methods were also used in metabolic studies. True autointoxication was induced by "forced feeding" with beef extract, *B. coli*, or heated fat added to the regular ration. By thus preventing normal digestion absorption and assimilation, "cytolysis and autocytolysis" occurred to supply the induced deficit. A large number of peptic ulcers in various animals were induced as an index of "auto-tissue extract" intoxication (1906, 1907, 1908, 1914) of the animals. Total starvation always resulted in autointoxication from autolyzed tissue ("Effect on Longevity of High Living," *Medical Exam. and Pract.*, August, 1907, p. 240-6, Trans. Oregon State Med. Assn., July, 1907). This intoxication was shown to be due to autolysis of the tissue by histological examination. 'The autolytic changes were evidenced by the faintness and disappearance of the nuclear staining." In both total and partial starved animals the chronic autointoxication was shown by early liver, kidney changes, later arteriosclerosis, peptic ulcers, hemorrhages and death. "Degenerative changes were found in all the organs of the body."

B. By Chemicals (1906-7): Mustard oil fed to animals caused similar phenomena, though the animals developed immunity to the effects of mustard oil emulsions (Trans. Tenn. State Med. Assn., Nashville, Tenn. (1905, p. 150)—(Experimental Gastritis, *N. Y. Med. Jour.*, October 25, 1902). The administration of chloroform, ether and alcohol for a variable length of time caused cell necrosis. The products of cell necrosis resulted in shock followed by degeneration and chronic metabolic diseases (1903). (Shock Produced by General Anesthesia, *Jour. A. M. A.*, May 2, 1903). Alcohol was found to be the sole factor indirectly. Chronic degenerative changes which produced autointoixcation long after the alcohol, was withdrawn (*North. Am. Pract.*, May, 1893, p. 227-230). Injecting chloroform, alcohol, and ether into muscle tissue (1919) and after cell necrosis, a short period when cell necrosis occurred, the tissue extract thus liberated was aspirated, injected into animals, producing acute or chronic metabolic disorders according to method of injection.

To extract the active principle cytost, we have used every organ and form of tissue from a large variety of animals. Various names have been given to this tissue extract. In the last twenty-five years of our research work on this topic it has been variously designated according to the method of extraction and the tissue or organs used. Thus, "mucous membrane bouillon" (1894), "stomach toxin" (1896), "muscle fatigue extract," "pylorum," 1903, etc. Furthermore, other names were given according to the peculiar biological reactions that occurred, especially on injecting this specific active principle into animals or liberating it from the tissues.

When shock and death was thus produced (injection or liberation of the toxin), it was called "shock toxin" (1897). When general or local fatigue, as atony or dilatation of the viscera, occurred by the injection of the same product, it was called "fatigue toxin," "waste products," or "metabolic poisons," metabolites, etc. This confusion is prevented and it becomes more clear by whatever method we use in the extraction to name the active principle "cytost" (from cytos, a cell).

Whether we extract cytost from the tissues by water, alcohol, or by incineration to an ash, cytost acts the same, depending upon the degree of concentration. The reaction that follows the liberation of cytost in the tissues, or injected subcutaneously, depends upon the degree of concentration of cytost and the anticytost present in the organism. Speed or velocity action is controlled by these two factors—cytost-anticytost reaction. This cytost-anticytost reaction which we have studied *in vitro* and *in vivo* for the last twenty-five years, makes simple and clear the whole biological trend. As Calkins laconically remarked (referring to this cytost-anticytost reaction in the cell), that here we have "a great principle, biologically unassailable, and the application of it is subject to no adverse criticism."

Experiments.—Experiments with (1) Tissue Cultures, (2) Protozoa, (3) Bacterial Cultures:

1. *Tissue Cultures.*—Cytost was extracted by autoclaving 10 grams of macerated or autolyzed tissue in 10 c.c. of water centrifuged and filtered; ignition of 10 grams of tissue to ash at or below 400° C., to which is added 1 c.c. of water for standard concentrated solution. Either of these methods gave the cytost reaction, the latter being free from "organic matter." Homologous-tissue cytost was used in all experiments except for the controls; heterogenous cytost tissue extract was added to the cultures. Three degrees of concentration was found to act each in a specific and definite manner.

Low concentration of cytost that excited cell division and metabolism is abbreviated as L. C.

Medium concentration of cytost which seemed to inhibit cell division and metabolism abbreviated as M. C.

High concentrated cytost which resulted in stopping cell division, resulting in death of the cell, abbreviated as H. C.

The exact concentration to produce these definite reactions was arrived at by the empirical results.

By conductivity experiments we are better able to make the concentrations and reactions more exact. Cytost was obtained from human tissue and from chick tissue for control in tissue cultures: 34 chick-cell cultures, 25 human-cell cultures, 384 transplants to which 308 cultures cytost L. C. was added; 76 cultures—no cytost was added and no cytost allowed to form in the cultures; 25 cultures H. C. cytost was added.

Result: The 308 cultures with L. C. cytost thrived and continued each to show active mitosis, while 76 cultures without cytost died. The 25 cultures with H. C. cytost also died the same as those cultures without L. C. cytost. Control by adding L. C. heterogenous cytost to the cultures which were negative in their action.

2. *Paramaecium Cultures.*—There has always been difficulty in obtaining pure cytost from paramaecium cultures—difficulty is in obtaining sufficient amount and free from foreign debris. On advice of Professor Calkins we grew the cultures in great numbers in small vessels for ten (10) days; gathered the slimy deposit on the surface and side of the vessels; washed and centrifuged the growths and evaporated to dryness. The residue was treated for extraction the same as ordinary tissue cells. To the tube cultures of paramaecium in hay infusion was added L. C., M. C., and H. C. of paramaecium cytost.

L. C. paramaecium cytost added to the tube cultures caused very active motility and cell division. Paramaecium cytost added to 50 tubes with L. C. cytost gave full, rich cultures. Controls in which no cytost was added, 50 per cent. less paramaecium, was noted in many of the tubes. It is difficult to prevent cytost from being liberated in these control cultures due to the death of some of the paramaecium. M. C. materially slows the activity of the paramaecium. H. C. paramaecium cytost causes entire death of the cultures within a few hours. No cultures with H. C. cytost lived twenty-four hours. The paramaecium first move in a narrow revolution, then rotate on their own axis, and finally become encysted and die. Heterogenous cytost from other animal tissue in the same concentrations used in these experiments did not produce the cell multiplication in low concentrations, nor death in high concentrations.

3. *Bacterial Cultures.*—In 1912 we grew in our laboratory on synthetic media *B. coli* in mass cultures and 80 grams of pure solid *Bacilli coli communis* was obtained.

To one gram of this solid *B. coli* was added 10 c.c. water and autoclaved, and also 1 gram incinerated at 400° C., and to the ash was added 10 c.c. of water. *B. Coli* cultures were made in the usual manner, to which were added L. C., M. C., and H. C. of *B. coli* cytost.

Considerable empirical work was done to determine the degrees of concentration of *B. coli* cytost to produce the variation and degrees of growth. On adding one-tenth dilution standard *B. coli* cytost to 10 c.c. tube cultures, the *B. coli* growth was stimulated. Dilution of one-tenth M. C. *B. coli* cytost inhibited growth, H. C. *B. coli* cytost added to the culture stopped growth of *B. coli*. L. C. *B. coli* cytost is negative in G. C., staphylococcus and streptococcus cultures. H. C. *B. coli* cytost stops all growth in 24 to 48 hours. The quantitative determinations will appear in a special communication on cell cultures.

Conclusion: In bacterial cultures high concentration of cytost inhibits growth and low concentration of the specific cytost stimulates growth. These experiments explain why "old cultures" die out. It is due to excess accumulation of the specific cytost from the dead bacteria.

Discussion on the Experiments with Cytost Added to Single Cell Cultures.—By combining experiments on single cell cultures, protozoa, and bacteria with similar experiments made on metozoa or in animal tissue, we may by these comparative studies more clearly interpret the biological reactions in all animal experiments, including man. As colonies of cells require products of their own kind, specific cytost to stimulate their growth and metabolism, it is more readily recognized why the same specific stimulation (cytost) is required for the growth and metabolism of the aggregation of cells in metozoa in all animals, including man. It also explains why excess of cytost caused a stasis or stopping of all growth, metabolism, ending in death. This brings us to the effect of specific cytost produced locally in animal tissue. This has a great practical bearing in wound healing and in the problems of overgrowth of tissue, including tumor growths.

Metabolism Experiments on Animals with Cytost Injected into the Tissues or Peritoneal Cavity.—Animals used—cats, dogs, and rats. The specific cytost was made either by direct water extraction from the tissues, using 10 grams of tissue to 10 c.c. of water, and filter. Secondly, by ignition to an ash and adding enough water for the desired concentration .25 c.c. of specific cytost to each 1,000 grams of animal was used (same concentration as tissue extract). We have selected fromour protocols ten adult cats that were injected over a period of from one to eight months. All the animals gained in weight and showed increased metabolism.

Control animals of similar weights and age and kept under similar conditions did not show the increase in general metabolic activity. Some of the animals showed an increase of nearly 50 per cent. gain.

TABLE No. 1

Number of Injections	Interval	Period	Original Weight	Weight Increased	Net Gain
10	2 weeks	2½ months	4230 grams	5355	1125
7	2 to 5 days	1 month	2880 grams	3140	260
5	2 to 3 weeks	3 months	2950 grams	3650	700
21	2 to 5 days	4 months	2180 grams	3090	910
5	2 to 3 weeks	2 months	2840 grams	3260	420

These are all aged cats that had reached maturity. There are males, females, and castrates. These animals have a general appearance equaled by very few if any that have not been immunized. There is a firmness of muscle, sleekness of coat, absence of fat (noticeable particularly in the castrates, which *always* become heavy with adipose). Playfulness, which is quite uncommon in old cats, as well as unusual courage. Their wounds healed without suppuration, even though they are kept in the same pen and no attention given to them. Used as controls in wound healing, lung insufflation, and shock experiments, they have demonstrated their immunity to disease and injury. Seven of these cats after two years are in the laboratory, healthy and vigorous.

This table shows the effect of more frequent injections of specific cytost, which is similar in effect to

the injection of high concentration as shown in Table No. 3. These frequent injections (either daily or in two or three day intervals) caused progressive decline in weight and general metabolism, and finally ends in death of all the animals.

TABLE No. 2

Amount Injured	Interval	Period	Orig. Wgt.	Wgt. at death	Loss	Disease Resulting
			Grams			
Subcutan. 1 and 2 c.c.	2-5 days	6 months	2970*	1420*	1550	Arterial Sclerosis
1 c.c. Subc. and Intraperitoneal	Daily	2 months	2335	1180	1155	Arterial Sclerosis
2 c.c. Intratracheal	2-3 weeks	1 year	3960	2550	1410	Arterial Sclerosis

2 c.c.	"	26 days	2260	1460	800	Chronic Lobar Pneumonia, Hepatitis, Nephritis

Summary of Experiments of Table No. 2.—Instead of a gain of approximately 50 per cent. in weight as occurred in some of the animals in Table No. 1 injected with low concentration at wide intervals, we have the direct opposite effect of 50 per cent. loss in weight by more frequent injections, or as shown in Table No. 4, high concentration effect. The progressive character of the metabolic decline ending in arterial sclerosis, nephritis, peptic ulcer, shows, as in the writer's earlier experiments, that products of tissue breakdown are the cause of these diseases. When the injections of cytost were made directly into the trachea, the cytost came in direct contact with the endodermal tissue cells derived from the endodermal layer of the embryo, there resulted at once rapid decline with chronic lobar pneumonia ending in death.

Intravenous injections of L. C. cytost act as high concentration because they come in direct contact with the endodermal cells of the splanchnic area as in the intratracheal injections.

TABLE No. 3

Number of Injured	Interval	Period	Orig. Wgt.	Wgt. at Death	Death in
High 3 Intravenous	5 days	15 days	2980*	2000*	5 weeks

*Grams.

The intravenous injections of cytost bring the active agent in immediate contact with the endodermal cells derived from the endodermal layer of the embryo. As these cells form the original alimentary tube from which spring the lungs, liver, and pancreas, it explains the intense primary reaction that takes place in the splanchnic zone. This seems also to determine the metabolic changes in the organism. The progressive loss in weight, and finally death, shows, as in the writer's earlier experiments in "shock," and similar phenomena (1893-1900), that the splanchnic area shows the primary "effect" of cytost, or what was formerly called by the writer "shock toxin."

To determine the effect of cytost liberated in the tissues in excess of the biological requirements, agents were injected that principally liberated cytost from the tissues. Chloroform, alcohol, and ether are very prompt in liberating cytost when injected into the tissues of the animal. The ferments trypsin and erepsin have a slower but similar effect. Death occurred in all the cases as shown in Table No. 4. "Very small doses," as was shown in the writer's previous work (1919), caused increased metabolism and eventual immunity.

TABLE No. 4

Agent Injected	Number and Intervals	Interval	Death in
Chloroform	2	6 days	13 days
Chloroform	1		2 days
Chloroform	24 small	2 and 3 days	95 days
Alcohol	3	1 and 2 weeks	28 days
Alcohol	3	4 days	1 month
Ether	1 Intra muscular		13 days
Ether	1 Intra muscular		34 days
Ferments	1		6 days
Ferments	1		62 days
Ferments	22 small doses	in 97 days	
	3 small doses	in 14 days	111 days

Experiments on the Local Effect of Injecting Cytost Into the Tissues of Animals (Metazoa).—Cytost was extracted in a similar manner, 10 c.c. water to 10 grams of tissue, and 10 grams of tissue ignited to an ash to which was added 1 c.c. of water.

Two methods in these studies were used: (1) Injection of homologous cytost directly into the muscle tissue. The galvanoelectric reaction that followed was observed and in 36 hours tissue was removed and sections made for histological examination. This was compared with the opposite side in which heterogenous cytost was injected, and in others in which no injection was made. The second method was the formation of a clean cut wound on the side of the animal, and into one side the injection of homologous cytost.

A third procedure was the study of animals rendered both actively and passively immune by methods described in the writer's earlier literature 1903) (1919).

Direct injection of homologous cytost causes within a few hours increased mitosis in the tissue. This was also noted if homologous cytost was liberated in the tissue by agents such as mustard oil (1894) (1903), chloroform (1903), etc. It usually required 24 hours before active mitosis by the latter method (1894) (1903) was manifested, and this occurs some distance from the site of the injection. The time required for liberation of cytost from the tissues and the specific reaction, mitosis, is about 24 hours.

Direct homologous cytost injections caused mitosis within 6 hours. The high millivoltmeter range shows marked increase in metabolic activity after the injection of homologous cytost into the tissues.

The comparisons made with heterogenous cytost must be reserved for special presentation with the exact readings.

Wound Healing.—In the study of wound healing we used for standard size a triangular wound 4 cm. base and 3 cm. each angle, made on the neck between the pole (occipital tuberosity) and whithers. The cat was usually used, though dogs and rabbits and rats were also used with corresponding size of wound. The rate of healing, as well as the character and time of healing, was noted.

Group 1—Ordinarily normal for control.

Group 2—Injection of homologous cytost L. C. into margin of the wound to stimulate cell division and cell metabolism.

Group 3—Active immune animals by repeated injection of "biological" cytost concentrations to create anticytost.

Group 4—Animals rendered passively immune with immune serum (anticytost).

This immune serum was produced by injecting cytost such as cat cytost into a goat. For detailed methods see author's literature.

SIZE OF WOUND

Grp.	First Week	Second Week	Third Week	Fourth Week	Fifth Week	Sixth Week
1	3x3x4	3x2 5x4	2 5x2x3	1 75x1 5x2	5x 75x1	Healed
2	2 75x2 75x3 75	2x2 5x3	3x2x2 5	1x1x1 5	Healed	
3	3 5x3x4 5	2 75x2 5x3	2x2x2 5	1x1x1 5	Healed	
4	3x3x4	2 74x3x3 5	2 5x2x2 5	1x1x1	Healed	

These experiments in wound healing represent the average of a large repeated line of experiments for many years by the writer, and indicates clearly that homologous cytost is the normal stimulant in wound healing, depending upon anticytost reaction in the organism. Only those agents that liberate cytost will excite wound healing. The cytost must be specific to the species. These facts explain why normal wounds heal and why cauterization liberates cytost and stimulates the sluggish wound to heal.

General Discussion.—It is clear that in all our experiments we have a specific active substance that is within the cell which, when liberated in low concentration, stimulates cell division and metabolism. Medium concentration or that above biological requirements slows or stops cell division and metabolism, while high concentration stops all cell activity, ending in death. This brings us to the studies in general cell division, growth and metabolism in the animal.

General and Special Pathological Findings.—In all of the examinations no infection resulted in any of the animals here reported. Where secondary invasion has taken place we have excluded them from this report. In chronic pneumonia a few of the animals showed bacterial invasion. Other animals that showed negative findings on postmortem examination showed the same pathological conditions. All our experiments indicate that bacteria were not responsible for the metabolic breakdown nor the death that followed.

Zone of Attack of Cytost.—The liver and lungs show primary reaction in the capillary area, and the endothelial cells in contact with the endodermal cells of the lungs, liver and upper alimentary tract. Later the kidney becomes involved, finally all tissues throughout the organism, through the capillary endothelial cells in close cellular contact. The brain is the least vulnerable next to muscle tissue, including heart tissue, but the endodermal layer that furnishes what we term the splanchnic area shows prompt response. The special and general pathology of most diseases find their beginning in this zone, *e.g.* cells that spring from the endoderm of the embryo.

Intraspinal Experiments with Cytost.—The brain and spinal cord are the most vulnerable and can only be secondarily affected to capillary reaction that result in asphyxia and starvation of the cells.

Direct injection of cytost into the cord produces local reaction and paralysis of the area supplied from the point of injection. In this group of experiments the most delicate index of the specific character of cytost is shown. The immediate response of paralysis by the injection into the cord of homologous cytost and the absolutely negative results of injecting heterogenous cytost into the cords demonstrates the remarkable specificity of cytost in the animal. Thus, as will be seen in the table, that cat cytost always caused paralysis, while dog, human, horse, etc., cytost, even in very high concentration were negative. Lion tissue cytost that belong to the same tribe was negative in cats.

Cytost was prepared from both homologous and heterogenous tissues by igniting 10 grams to an ash and adding 1 c.c. of water. This concentration being called M. C., higher concentrations H. C., and lower concentrations L. C. Only the supernatent solution of ash was used for injection after autoclaving.

Two methods of studies were used in these experiments:

1. Homologous cytost, injected in $^1/_4$ c.c. doses (M. C.) all along the dorsal and lumbar region. That is, each homologous animal was injected with $^1/_4$ c.c. cytost either at the first lumbar space, the second, etc. In each case the animal was anesthetized, the site of injection clipped, shaved and disinfected. The sterile needle inserted and the entrance into the spinal cord was determined by the clear spinal fluid. In a similar manner experiments with H. C. and L. C. were made.

2. Heterogenous cytost (lion, horse, dog, rat, chicken, human, pig) was prepared in the same manner and in the same concentrations as the homologous cytost and also injected in control animals with the same technique.

Homologous cytost (M. C.) using the above dosage produces the immediate paralysis of the posterior limbs, bladder, etc., if injected into the lumbar region, and paralysis of the anterior limbs if injected into the dorsal region, always attended with the following symptoms: drawing up of limbs, arch back, followed by delirium, biting of affected part, etc., then coma (shock), and gradual recovery with complete paralysis. These symptoms last respectively from 5 to 15 minutes; second, from 5 to 20 minutes; third, from 15 minutes to 12 hours. The animals invariably die in two days to two weeks, giving always a typical postmortem picture. In all cases smears and transplants showing negative results to bacterial invasion.

H. C. homologous cytost produces a shock death from a few seconds to 2 to 3 hours.

L. C. cytost produces the same type of symptoms, the period of delirium and clonic convulsions being of longer duration, due to motor stimulation. The animal may show incoordination for two or three days, but he will eventually recover.

Heterogenous cytost (H. C., M. C., or L. C.) in almost every case produces a tremendous motor stimulation for convulsions clonic in character on the onset, and becoming tonic toward the termination. There is no first phase as in the homologous cytost, the second phase (excitement) lasting from 20 minutes to an hour, the period of coma (shock) lasting only a few minutes. The animals invariably recover, with no paralysis.

On the second or third injection of heterogenous cytost (H. C. and M. C.) in these recovered animals, paralysis results, although not as well marked as in the homologous cytost experiments. This remarkable phenomena is no doubt due to the liberation in these sensitized animals of homologous cytost by the first injection of the heterogenous cytost.

Remarks and Conclusion.—To determine with exactness and precision the immediate specific effects of high and low concentration in animals we have thus used the spinal canal at different levels for the cytost injection. The results show, as seen in the protocols, that we have here a most delicate indicator of the highly specific character of cytost which is specific only to the species. It shows that animals of the same tribe as lions, injected into cat, produces negative results. Animals may be rendered artificially anaphylactic to foreign cytost, but this depends on the liberation in the animal of homologous cytost combining with the foreign cytost previously entering the organism. The reaction on the injection of the foreign cytost in sensitized animals appears to be due to the action of the liberated homologous cytost.

As was clearly outlined with reference to the writer's previous experimental work in the introduction of this article, we have demonstrated an important biological principle, that low concentrations of tissue extract (cytost) stimulate cell division and metabolism and that high concentration produces disease and death.

We have shown by the experimental research covering a period of twenty-five years a new biological principle that a cell extract we have named "cytost" excites cell division and metabolism in biological concentration and in high concentration produces disease and death.

Conclusion on Cytost: Low concentration of cytost—Physiological. Medium concentration of cytost—Pathological. High concentration of cytost—Lethal.

Immunity: Active immunity—Cytost injected in animal. Passive immunity—Homologous cytost injected in alien animal.

Newborn Babies as Diphtheria Carriers.—During an epidemic of diphtheria in a lying-in institution, the newborn were tested for the presence of diphtheria bacilli. Forty-three were found to be carriers, and of this number ten developed the disease and six died. However, but one of the six died of diphtheria outright, as sepsis was the actual cause of death of four, although diphtheria was doubtless a contributory cause. —*Zeitschr. f. Kinderheilkunde.*

SOME MOUTH AND JAW CONDITIONS RESPONSIBLE FOR DEFECTS IN SPEECH.*

BY JAMES SONNETT GREENE, M.D.,

NEW YORK

DIRECTOR OF THE NATIONAL HOSPITAL FOR SPEECH DISORDERS

BEFORE taking up some of the mouth and jaw conditions that cause defective speech, I would like to say a few words about normal speech.

Speech is the faculty that more than any other distinguishes man from the brute creation. Man alone has sufficient intelligence to create within himself this particular vernacular or means of expression. Thought has been called the motive power of the world, and speech is the natural vehicle of thought.

It even forms an essential part of all abstract thinking, and thus a tool of the mind in precisely the same way as the instrument is the tool of the surgeon; and it is quite as important to our mental processes as instruments are to surgical work. Good speech, therefore, or that which is unhampered by even minor defects, is requisite to the highest mental and physical development.

Man being primarily a social animal, it is to speech that he resorts in every phase of his association with his fellows. Herein is the expression of his personality, and from that standpoint alone the importance of speech is inestimable.

Human happiness is an expression of mental and physical health, and where there is no happiness we find repression, and with it lack of health and contentment; and as conditions are to-day, we find even in our educated element, abnormalities of speech which indeed need not be.

Speech is the faculty of uttering articulate sounds or words. Speech is made up of a limited number of sounds produced by definite positions of the vocal organs. Words, though each be unit, are made up of combinations of a limited number of sounds.

There are a number of theories advanced as to how articulate language came into existence. The work of anthropologists and linguists, especially the former, supports the progressive evolution theory, which briefly stated is—that articulate language is the result of an elaboration in the long procession of ages in which there occurred three stages—the cry, vocalization, and articulation. The cry is the primordial pure animal language; it is a simple vocal inspiration without articulation; it is either a reflex expressing needs and emotions, or a higher stage, intentional (to call, warn, menace, etc.). Vocalization, emission of vowels, is a natural production of the vocal instrument and does not in itself contain the essential elements of speech. Many animals are capable of vocalization, and in the child the utterance of vowel sounds is the next stage after the cry.

The conditions necessary to the production of speech arose with articulation and it is intelligence that has converted the vocal instruments. For whereas correct intonation depends upon the innate ear, which is able to control and regulate the tensions of the minute muscles acting upon the vocal cords, it is intelligence which alters and changes the form of the resonator by means of movement of the lips, tongue, and jaw in the production of articulate speech.

The simple musical instrument in the production of phonation is bilaterally represented in the brain, but as a speaking instrument it is unilaterally represented in right-handed individuals in the left hemisphere of the brain and in left-handed individuals in the right hemisphere.

Recent statistics show that in New York City out of 650,000 children in the public schools, 30 per cent. at least were two grades behind that which they should have attained. Almost all of these pupils are suffering from some defect of eye, nose, mouth, or throat. This does not include statistics as to the number of children, aside from adults, who suffer from some defect of speech, for until recently it has never been considered of enough importance to take this condition into consideration.

Also there are no statistics as to the number who suffer from mouth or jaw conditions in conjunction with their defect in speech. The percentage is appalling and the reason for our lack of knowledge is the lack of co-operation between those who treat mouth conditions and those who treat speech conditions. In the near future there will be a more complete understanding and association between these two specialties—defective speech and dentistry.

Looking into the dentist's field from the anatomical point of view, I find that dentistry plays a very important role in speech. Let us commence with a troublesome member, one that every dentist has to contend with—the tongue. It has always been considered to be the most valuable and important instrument for normal speech; nevertheless, it has been demonstrated many times that defects of the tongue very often produce only minor defects of speech. Even with a total loss of the tongue it has been shown that one can speak fairly well, though some of the sounds are missing.

The result has been accomplished by the substitution of the other parts of the mouth for tongue motion. Thus, for example, in the sounds of *k* and *g*, where the action is based upon the existence of the back part of the tongue coming in contact with the back part of the palate, there may be produced instead of this tongue action, a glottal catch far down in the throat, or more definitely, above the exit of the larynx, simulating the sounds of *k* and *g*.

Though seemingly incomprehensible, the consonants *t*, *d*, *n*, *l*, which depend mainly on the contact of the tip of the tongue with the hard palate, can also be produced where a tongue defect exists, by the substitution of lip action for tongue action. If one retracts the lower lip and presses it against the alveolar margin of the upper jaw, the glottal catch is made the same as if the tongue were used, the lip not even completely retracted, but its "mucous membrane" is used for a catch about one-sixteenth of an inch below the edge of the lip.

The *s* sounds, although not formed as exact and sharp as when the tongue is used, can be made sufficiently clear by the correct approximation of the upper and lower teeth.

Even the sound of *l* can be heard fairly well when there is a complete loss of the tongue, as remain-

*Read before the section on Oral Surgery—First District Dental Society, at the New York Academy of Medicine, on January 5, 1921.

ders of the genioglossus are always able to lift the bottom of the mouth, thus forming an impediment in the center of the emanating sounding air column, since it is not absolutely necessary to have a complete parting of the air current in order to produce this sound.

The sound of *r* very often produces difficulties but can be readily substituted by a labial or a laryngeal *r*. The labials *b*, *p*, *m*, *v*, *w* can be naturally produced because the tongue is not used at all in the production of these sounds; the *b*, *p*, *m*, *w*, being formed by the lips only, and the *f* and *v* by the lips and teeth.

From these examples one can readily deduct that although the tongue may be completely extirpated, one does not necessarily lose the power of speech, that is, it proves that the tongue is not the essential factor for the production of speech; however, I might add that the tongue is an important factor in determining the form of the lower jaw.

Defects of the lips cause disturbances of speech only when greatly affected.

The relation or connection between the palate and teeth is so close that therapy of the palate without therapy of the teeth, or vice versa, cannot be thought of. But speaking of the teeth alone in their significance for speech I must say that in most cases they have no direct causal effect upon the production of speech sounds because almost all sounds can be formed after a fashion without the use of the teeth, except the hissing sounds of *s* and *z*, where the position of the teeth is of importance.

The existence or non-existence of teeth is not so important for good speech as the shape and roof of the mouth, which acts as the sounding board and upon which normal speech greatly depends.

Now let us see why there is such an intimate relationship between the teeth and the palate. We distinguish anomalies of the shape, number, and position, besides structure of the teeth. The most important to us are the anomalies of the position of the teeth on account of their interference with the normal biting ability.

We point out the protruding or direct bite, otherwise called the under-bite; usually the lower jaw is too large or it is pressed a little forward out of its regular articulatory position. Quite often this is caused by habit or from imitating the speech of others. It is particularly noticeable in many people whose whole articulation seems to depend upon the lower jaw being pushed forward, thereby altering the whole tone or timbre of the speech.

Another abnormality is the projection of the upper row of teeth, the so-called overbite.

Again, there is the sliding bite produced by wrong positions of the teeth; and the open bite, which is caused by the alveolar process of the molars being too big. The front open bite is well known to all of us. Less consideration has been given to the side open bite which has frequently been found in certain speech disturbances.

Besides the effects of such faulty positions, a dislocation of a faulty tooth may hinder the proper coordination necessary for speech. For instance, a front tooth pressed backward out of its alignment may hinder the laying of the tongue on the alveolar margin and produce a hissing sound where there should be a closed or stopped sound.

It is well to realize the fact that speech plays an important role in producing a normal condition of the alveolar process and position of the teeth; for before the cutting of the permanent teeth, the teeth have but a shifting position in the alveoli.

We can compare them to the growing of weeds—just where there is a space a weed grows, and just where there is a space a permanent tooth develops. Even the cutting is arbitrary, for sometimes some teeth appear curved, others the reverse, but we see that after some time they regulate themselves and take their normal places.

We can also state that the regulation of the teeth is aided through speech, by the concerted action of the lips and tongue, the lips pressing on the teeth from one side and the tongue pressing the teeth from the other side. This is contrary to the general idea that the teeth have influence on speech instead of the speech having the influence on the teeth.

This process is similar to what occurs in the formation of the head, the form of the skull depending on the growth of the brain, and not the growth of the brain depending on the form of the skull.

We realize that the position and regulation of the teeth are influenced by the motion produced when chewing, by the articulation, and by speech. It is probable that the misformation of the position of the teeth frequently seen in idiots is influenced by the lack of one or more of these performances, of course this not being the only cause. We notice that in an idiot the lower jaw hangs down, the tongue does not lie tightly on the roof of the mouth, therefore the palate does not take on its V-shaped angle, and the teeth do not grow and stand apart.

In the low grade idiot the mouth is always hanging open and the speech is entirely lost. If we disregard the phenomena of the idiots, the most frequent cause of the anomalies of the positions and cross positions of the teeth is the lack of space. The alveolar process is too small for the teeth, and therefore it has been often suggested to extract the first lasting premolar in order to give room for the other teeth.

We can readily see the direct relation of the teeth and palate from the changes that take place in the palate through the anomalies of tooth position. In the relation of the teeth to speech the form of the hard palate must always be taken into consideration.

If we consider that the lack of space is the most important cause of the anomalies of the positions of the teeth, then this lack of space can produce the following effects: It can produce a pushing apart of single teeth from the row; and it can produce a curving position of the teeth in a horizontal or in a vertical curve.

The pushing of a tooth from the row may produce defects of articulation which are of minor importance.

The arch positions are of greater importance. Observing the teeth of the upper jaw from below one notices that they are placed in a more or less oval half circle, or in other words, in a horizontal arch. If for some reason the teeth of the upper arch do not properly articulate with the teeth of the lower arch, lateral gaps are formed. These gaps prevent the tongue from correct approach and cause faulty noises when speaking.

The relations are more obvious with the vertical

curves. The vertical curve as we observe in the open bite from the front, hinders the natural tight closing of the teeth necessary for enunciating *s* and *z*, etc., causing a *th* sound in place of an *s* sound. If these vertical curves in the open bite occur on the side they cause a very disagreeable lateral lisp, which I shall refer to later.

We will now turn our attention to the question, "Which speech sounds are connected with the teeth?"

The first to be considered are the sounds of *f* and *v*, known as the labiodental sounds.

Variations occur at the overbite as well as at the underbite. When there is a prominent overbite, as where the incisor teeth of the upper jaw protrude very much and the upper teeth rest upon the lower lip almost constantly, the patient looks as if always pronouncing the letter *f*. It is naturally very difficult and rather uncomfortable for him to coaptate his lips.

When it is difficult for the patient to coaptate his lips it is almost impossible for him to make the labial sounds, *b*, *p*, *m*.

Another point is that the upper lip, not used any longer for closing, leaves the upper row of teeth uncovered and always visible to the eye, thus making the person look very unattractive.

In a very pronounced underbite *f* is often formed between the lower row of teeth and the upper lip. We get such an *f* formation in children having a double harelip whose upper jaw is generally retarded in growth and the lower jaw protrudes. The retraction of the upper jaw depends upon the tight scar of the double harelip.

Also, the underbite can be so pronounced that the articulation between the lower row of the teeth and upper lip is even applied to the labials, *b*, *p*, *m*. When this is the case the lower lip protrudes so far that it seems to be hanging free in the air, giving to the face, especially in profile, a very awkward appearance.

The next sounds of importance to be considered are the hissing sounds of *s* and *z*.

We will note how abnormalities of the teeth, loss of alignment, articulatory disturbances, affect the production of the sound *s*.

Defects of the *s* sound are classified as Sigmatism. The term Sigmatism is applied to a dental form of Dyslalia which interferes with the correct formation of the friction sounds—*s*, *ss*, *sh*, *z*, *zh*, and also of the combination—*ps*, *ts*, *z*, *ms*, *ns*.

Sigmatism is always attributable to a wrong position of the tongue, which is occasioned, as pointed out, by anomalies of dentition and maxillary articulation. The defect occasionally originates at the period of second dentition. Sigmatism develops preferably when the upper or the lower incisors are missing.

Young children very often have this defect, if eruption of the incisors is delayed. This defect may be permanent, but if due to second dentition, is usually transitory providing that the eight incisors are completely formed.

There are various forms of sigmatism. The interdental when the patient says "tshop" for "stop," on account of his open dentition; the addental form where the patient says "thoap" for "soap," depending upon the protrusion of the upper or lower maxilla; lateral sigmatism due to an unilateral or bilateral inward or outward displacement of the jaw causing an excess escape of air.

We thus see that when teeth are out of their alignment they generally impede the motion and formation of the tongue, especially where a high palate exists. The sounds of the second and third articulation sphere are more or less strongly impeded, the *s* more so than the other sounds.

An interesting difficulty is very often encountered when a dentist repairs the teeth and these repairs produce great difficulty in speaking. The patient has to become used to the new proportions of space for his tongue until he again speaks as usual; but it sometimes happens that in cases of this kind the speech difficulties become permanent speech disturbances.

As for example, let us presume that the tongue is so near to the alveolar margin of the upper jaw that with the color experiment only a very narrow groove appears and that in such a case a bridge for the upper incisor teeth makes the space for the tongue still smaller, then the air current will not be able to pass through the groove needed for the *s* formation; the tongue will lie too tight to the foreign body and a lisp more or less distinguishable will be heard.

I have had several just such patients under treatment. These cases were very annoying to the dentist because he was blamed for the condition, but of course, blame is out of the question unless a full guarantee against speech disturbance has been given; but one must admit that the occurrence is rather unpleasant. In cases under contention the remedy is simple enough. The patient is reeducated in the proper adjustment of his tongue for the defect and the speech disturbance disappears.

The next sounds to be considered are *t* and *d*. When *t* and *d* are spoken, unnecessary disturbing hissing noises are very often heard. This is usually due to the speaker's teeth being out of alignment. I have had cases where a side incisor tooth, being pushed back out of the row, hindered the tight approach of the tongue to the alveolar margin of the upper jaw in the act of forming a *t*, thereby causing an *s* sound to be produced every time a *t* or *d* was spoken.

This occasionally was the cause for rather amusing and complicated statements, for when the patient wanted to say, for instance, "Do not tell anyone," he would say, "Do not sell anyone," and instead of saying, "I want my dinner," he would say, "I want my sinner."

Defective enunciation can also be produced by the arches, especially the side arches. In 92 per cent. of all cases having a lateral lisp we find that the larger arch is always on the lisping side. That is taken to indicate that a certain relationship exists between the side arch and lateral sigmatism.

Attention has been called to this fact and it has been recommended to eliminate the arch and make room for the other teeth by the extraction of a tooth. This has been done, but the lateral sigmatism was not affected. We therefore see that the arch is not always the necessary cause of the lateral lisp.

A word about the relationship between the position of the teeth, the roof of the mouth, the tone of the voice, and the quality of speech. Without doubt

the roof of the mouth has a very great acoustic influence upon the tone of the voice and the quality of speech. The general clearness of the vowels and consonants is influenced by the roof of the mouth.

The height of the palate depends on the perfect or imperfect development of the nasopharynx. Every case of high palate demonstrates a certain amount of respiratory incapacity and local infection, and this in turn always has influence on voice and speech.

The question of voice and speech in cases of cleft palate is a matter of vast importance.

In the first place, before operation, the voice is seriously impaired by the malformation of the mouth and nasal resonators. In addition there is a nonexistence of the soft palate whose function is to check the air passing into the nasal cavities and to work in contact with the tongue in the production of the *k* and *g* sounds.

Where the hard palate is cleft, *consonants* depending on the contact of the tongue and hard palate, such as *t, d, n, r, l,* are mutilated. No doubt when treating patients having congenital clefts of the palate, when making various kinds of plates, you have noticed that the speech of those patients was more or less affected; but what I wish to point out is that proportionately the speech or voice defect does not coincide with the size of the palatal defect; for there are small defects, small openings which one sometimes sees at the junction of the hard and soft palate produced by syphilis which greatly interfere with the production of speech, while in some large defects of the palate, even with harelip on both sides, one will find tolerably good speech without even resorting to the use of mechanical interferences.

If one will carefully test cases of this kind there is usually found some existing conditions of the nose or throat responsible for this anomaly. An enlargement of the nose and its parts; or adenoid vegetation in the nasopharynx is sufficient to produce this condition by acting as a substituting medium for the function of the missing palate, and thus making possible for the formation of speech sounds.

Operations for repair, with the details of which you are already familiar, give as near a normal condition as is possible to obtain under existing circumstances.

The question—whether the closure of the cleft remedies the defective articulation—can be emphatically answered in the negative; but I might add that the resonance of the voice becomes more normal simply through the improved anatomical status. In nearly every case speech training is not only advisable but is absolutely necessary.

Following the operation the cleft palate the patient usually presents one or all of the following defects of speech.

1. During the production of many of the consonants the familiar nasal resonance and nasal snort are heard. This is due to the lack of elasticity and mobility of the soft palate. The levator muscles cannot raise the palate with sufficient power. The soft palate ordinarily would have regulated the exit of the air through the anterior nares, but on account of its inefficiency the alæ of the nose come into play and become compressed, resulting in more or less severe facial distortion. This condition is the most difficult to overcome.

2. The nonexistence of the consonants *k* and *g*. Through lack of contact between the back of the tongue and the soft palate, on account of the inelasticity of the soft palate, following operation.

3. The nonexistence or indefiniteness of the consonants *l, t, d,* on account of insufficient contact between the front of the tongue, the hard palate, and the alveolar margin behind the front upper teeth, due to insufficient surface being presented to the tongue. Faulty dentition also aggravates this condition.

4. Where there is a harelip, difficulty in the production of the consonants *b, p, m, w,* due to the tensed upper lip not being able to come in close contact with the lower lip.

5. The production of the consonant *s* is nearly always accompanied by a very unpleasant nasal sound on account of the soft palate working inefficiently. Following an operation it occasionally happens that the soft palate is too short to reach close to the posterior pharyngeal wall, consequently, most cleft palate patients possess to a more or less degree a permanent rhinolalia-aperta voice, a nasal voice, even after everything possible has been done both by operative and speech training measures.

The difficulties of the speech of these patients are nearly always increased by abnormal positions of the teeth and of the alveolar processes in relation to the bodies of the bones to which they are attached. Their correction must be taken care of before the best results in speech can be attained.

Speaking about voice and speech results in these cases, I wish to call to your attention a special phase which these patients present, the condition—amusia. All cleft palate cases suffer from amusia, that is, a disturbance in the musical faculty. They all demonstrate one definite form of amusia, that of tone-deafness. Defects in the musical and speech faculties may coexist or exist independently of each other. The independent occurrence of disturbances in the musical faculty points to the existence of a separate center presiding over the musical memory.

No progress can be made in the elimination of nasality of cleft palate cases until the patient's musical sense has been developed to such a degree that he or she realizes the difference between nonnasal and nasal intonation. As soon as this takes place the patient strives for purer intonation and gradually the nasality diminishes until it is to all intents and purposes completely lost. In other words, he has lost his tone-deafness and of course does not suffer from amusia any longer.

For some years past I have had experience in the speech training of patients operated upon by Dr. MacKenty. Those patients presented good palate surface and a minimum amount of scar tissue. I presume the result of his particular style of operation, in comparison with other styles of operation seen in other patients who have come to me from various parts of the country and present a great deal of scar tissue, thus making the palate nonpliable and inelastic. This, of course, makes the production of a normal voice and speech more difficult.

In the consideration which I have put before you I have but given a brief survey of the subject, but I hope I have succeeded in making clear the im-

portance of the cooperation of the two specialties—dentistry and defective speech.

Every dentist or dental surgeon should have general working knowledge of the physiology of speech and some of the speech anomalies due to mouth conditions; and I hope that in the future we will do here as in the dental colleges abroad, that is, the education of dental students will include a course in the physiology of speech and phonetics.

Through cooperation we may reasonably feel that we can look forward to the general betterment of mouth, voice, and speech.

113 East Thirty-seventh Street

SEA BATHING AND THE EAR.

By ALEXANDER ROVINSKY, M.D.,

NEW YORK.

The incidence of various ear affections during the sea bathing season has so far attracted comparatively little attention from either the general practitioner or the otologist. This is rather puzzling, inasmuch as the number of ear cases in special ear clinics, as well as under the care of every more or less busy aurist in private practice, point to an undoubted increase in ear troubles that can be directly traced to bathing in the sea, especially in the months of July, August, and September, and the variety of affections runs the whole gamut of pathological ear conditions, from a comparatively innocent circumscribed furunculosis of the external ear up to an involvement of the mastoid with all its possible consequences. The subject deserves special interest, the more so as proper instruction of our patients and a little pains on the part of the medical man in becoming familiar with the harmful possibilities of improper sea bathing may prevent many an acute ear disease, as well as dangerous exacerbations of chronic dormant conditions. Elementary as it may seem, it must nevertheless be observed, *en passant*, that the entrance of the sea water with its contaminating contents into the middle ear is not effected through the external meatus (assuming the drum to be intact), but by way of the Eustachian canal, which is directed downward, inward, and forward, and whose pharyngeal opening is somewhat deeper than the opening into the tympanic cavity. It is assumed that the walls of the canal approximate each other in its middle portion, but open up during the act of swallowing. We have all of us experienced while diving or when submerged by an oncoming wave the irritating effect of the sea water entering through the mouth or nose into the posterior pharynx, as evidenced by a sense of choking and by uncontrollable coughing, and an impulse to swallow, thus forcing the water into the middle ear. To be sure, a defective drum or one absent altogether, presents an even more direct avenue to the entrance of the sea water. I doubt if the presence of a little sea water in a healthy external auditory canal, with no break or abrasion in the continuity of its tissue and with an intact drum, can do any harm, although I have seen several cases of both circumscribed and diffuse hyperemia of an otherwise sound external canal after rather prolonged bathing and diving; for want of a better explanation I ascribed this condition to a possible desiccating effect of the salt water on a peculiarly predisposed mucous lining. This trifling condition is at times excruciatingly painful, but fortunately easily controlled either by an application of a strong (from 20 to 50 per cent.) solution of silver nitrate, or by the insertion of an alcoholic plug, as I will explain later.

A patient who has thus forced some water into the middle ear will complain of stuffiness, somewhat impaired hearing, occasionally slight tinnitus, but usually no pain. All these symptoms point to a mild degree of irritation of the Eustachian canal due to obstruction, which in its turn disturbs the normal equalization of the air pressure between the external air and the middle ear space; the ventilation of the tympanic cavity is thus interfered with and sound transmission is affected. In a recent case and one of normal Eustachian and middle ear, careful catheterization of the canal, possibly repeated within twelve or twenty-four hours, will usually be sufficient to empty the tympanic cavity of the few drops of the sea water and bring it back to its normal condition. When of longer duration it may cause an Eustachian catarrh which may spread to the middle ear. It may not be amiss to note here that the introduction of the Eustachian catheter is greatly helped, even in experienced hands, by a preliminary cocainization of the respective nasal fossa, as well as the pharyngeal opening of the tube.

Otitis externa, whether circumscribed or diffuse, when brought on by sea bathing, does not differ clinically from that induced by other etiological factors, although as a general rule I have found them, with a few exceptions, of a milder type. A day or two after bathing the patient will complain of discomfort or even slight pain, possibly itching in the ear; this latter impels him to scratch the respective spot either with the bare finger, or, if deeper situated, with a pencil point, match, toothpick, or what not. As a result the condition is aggravated and the pain becomes more and more marked. It is to be observed that the nearer the inflammation, whether a mere hyperemia, infiltration, or a fully developed matured abscess, to the meatus of the external auditory canal, the slighter the pain, though as a general rule the tenderness is very pronounced, no matter how slight the affection. Anatomically, the soft structures situated more externally yield more readily to stretching by infiltration as compared with the deeper portion of the canal with its unyielding osseous framework. In pronounced cases the pain is not limited to the ear alone, but may be felt diffused all over the side of the head, and even down the neck, and is considerably aggravated by the process of mastication—a very characteristic symptom which is frequently of great assistance in differentiating this condition from an acute middle ear disease. Hearing is usually not affected, except in those rather severe cases where the swelling is so extensive as to cause by its very size occlusion of the canal, and thus interfere mechanically with the transmission of sounds. We often find considerable swelling behind the ear, so much so as to push the lobe forward, thus simulating a possible mastoiditis. In severe cases attended by fever, headache, general malaise, and an obstructed canal that prevents the inspection of the drum, there may arise some difficulty as to the differential diagnosis between a severe external otitis and an im-

pending mastoid. The onset, the previous history, pain on drawing up the auricle, a very characteristic symptom present in external otitis, pain on moving the jaw, and so on, will assist in differentiating between the two conditions. I have met but very few cases of severe external otitis that could be directly ascribed to surf bathing.

As regards treatment I have for several years past resorted to the simple expedient, in cases of hyperemia or even when there is some infiltration, of inserting a plug of sterile gauze saturated with alcohol. The inflamed area is first painted with a solution of silver nitrate, and the plug should be inserted to fit in snugly, but not so tight as to feel uncomfortable. The first two or three minutes the patient may complain of increased pain, but this soon gives way to a sense of diffused warmth attended by considerable relief; the patient is instructed to keep the dressing moist by saturating it every hour or two. I have found in a great many cases gratifying relief from this simple application within 24 or 36 hours. In more advanced cases when the infiltration of the tissues is considerable, or where pointing calls for incision and curettage, as in deeply situated furuncles, this dressing keeps the wound clean, and is continued for a time until the healing is started. The alcohol evidently acts as an astringent and desiccating agent which is at the same time somewhat anesthetic and slightly antiseptic; while the plug acts mechanically by keeping the walls of the canal separated, thus preventing autoinfection. A point to remember in cases that require incision is that the latter should be deep enough to reach the bone or the cartilage; this would in many cases require a general anesthetic, as local anesthesia is not quite satisfactory.

I have devoted some space to the description of the above condition for the reason that it can be recognized with comparative ease, and is quite accessible to treatment by the general practitioner. For the elucidation of symptoms and treatment of other conditions of the ear that may be brought on by sea bathing, such as acute catarrh of the Eustachian canal, acute myringitis, acute otitis media, exacerbation of a previously existing chronic otitis, and so on, I would refer the reader to any standard textbook on Otology, for they do not as a rule differ from similar pathological states brought on by other pathological factors. And here I cannot forego the opportunity of urging, and this can never be too strongly done, the necessity, when indicated, of a timely paracenthesis as a sure preventive of serious trouble. The comparative harmlessness when properly performed of this little operation should be impressed on the mind of the public; nor should there be any hesistancy on the part of the attendant to repeat the incision in a few days so as to be sure of unhampered drainage.

Among the dormant conditions that seem to be called into activity by sea bathing we find mostly cases of purulent, and also sometimes catarrhal, middle-ear disease. I have heard it repeated by patients in an almost stereotyped way: "I felt tolerably well until I took a dip," and I recall a few cases, one of which, taken as a type of this class, was very striking, in which the "dip" was followed by very serious consequences. This was in a man of thirty who has had a purulent middle ear for some ten years with an extensive central perforation in the drum, and whom I had under my care for several months for a recurring discharge. Twenty-four hours after bathing he showed unmistakable signs of active exacerbation, and notwithstanding all my efforts to control the condition he developed within a few days the classical symptoms of mastoiditis.

I am not prepared to say in what way sea bathing, and possibly also river bathing, exerts its deleterious effect upon the structures of the ear: whether it be the irritation caused by the constituent salts of the sea water, the trauma induced by the impact of the never ceasing ebb and flow, a peculiar sensitiveness of the organ of hearing to these influences, or what not, singly or combined. The mere presence of any aqueous solution, whether salt or medicated, when driven with sufficient force into the middle ear may alone be sufficient to start up an Eustachian catarrh or even a middle-ear inflammation. The practice of snuffing up into the nose salt water from one's palm as indulged in by laymen and even recommended by some physicians, has been held justly responsible for many an attack of otitis media; the same may be said to a limited extent of forcible atomization. It is a good rule to instruct the patient when using an atomizer to keep the head turned to the side opposite to the one that is being atomized, and have the mouth open, thus precluding the possibility of swallowing.

It should be remembered that sea as well as river water, and especially near the shore that contains outlets or discharges for sewers, contains a great many disease-producing organisms; in fact, at some seashores one actually bathes in diluted sewage, and while the high tide may carry it away into the ocean, the low tide maintains it there with all the flotsam and jetsam of the sea. Our system of sewage disposal, even in the large seacoast towns, is far from ideal, and the bather is very often apt to swallow the germ-laden sea water, which on being forced into the middle ear is sufficient to excite an inflammatory condition *de novo*, or call into life a long dormant chronic affection.

As to indications and contraindications for sea bathing so far as the ear patient is concerned, it would be not only cruel but decidedly tactless to advise every sufferer from any ear disease to abstain from bathing. And what is more, the advice will not be followed by the majority of patients. It stands to reason that no sufferer from any acute middle-ear disease should be permitted to bathe; the very sojourn at the shore may be harmful to such. In fact, among the older writers there was a prevalent opinion that no sufferer from any ear affection should be allowed to sojourn at the seashore, and this claim has been substantiated, in their opinion, by the presumed deafness or hard hearing so frequently found among those living constantly at or near seashore towns. According to others, the pearl fishermen or sponge divers are subject to accentuated auditory troubles which, however, should be ascribed to the frequently changing abnormal pressure in the tympanum induced by their occupation.

On the other hand, sojourn at the sea and carefully supervised bathing has been claimed to be of great benefit to the poorly developed and anemic of any age, and especially in a certain class of children of syphilitic or tuberculous tendencies. And in

these latter subjects in whom the ear affection is apt to begin rather insidiously, blooming forth as chronic from its very incipiency, a great deal of good can be accomplished, to be sure, before extensive destruction of the tissues has set in, by sojourn at the seashore, as well as bathing, in addition to local treatment. The effects of sea bathing are not to be ascribed to the constituency of the seawater contents, but to other conditions that in their total aggregate tend to exert a powerful psychic and physical stimulus on the metabolism of the system, and cause a heightened activity in every organ of the body. There is first of all the change of the environment, the psychic effect of carefree sporting life, an element of enjoyment of great importance, exposure to sunshine, running and romping on the beach; all of these result in a number of peripheral stimuli with a consequent series of reactions. The overstimulated and overwrought city dweller is beneficially affected by the very aspect of the seaview, which induces a restful mental state. The effects of immersion in the water are due to the variability in the temperature of the sea and the air; as the body is wholly or partly immersed in the water, this variability is increased by the motion of the air, the winds, and the water, thus constantly stimulating the peripheral nervous system; then there is the impact of the waves against the body, the movements of the body in wading, diving, swimming, etc. The humid, pure air of the seashore is under greatest atmospheric pressure, and consequently is rich in oxygen. It is thus evident that sea bathing exerts a very pronounced effect on the nervous system as well as on nutrition in general. This latter effect is often very marked, and with the stimulated metabolism there is an undoubted tendency toward a diminution of chronic discharge, and absorption of exudates, as found in both purulent and catarrhal chronic otitis media; and provided no great destructive changes have occurred in the organ of hearing, improvement may be expected in certain selected cases.

Conclusions.—In a general way people who suffer from any defect that interferes with normal breathing, such as marked deflection of the septum, hypertrophied turbinates, especially the posterior tips, tonsils, adenoids, or any other retropharyngeal growth, should be warned against the possibility of ear affections during the sea bathing season, and the least appearance of inconvenience or pain in the ear calls for immediate consultation with the family physician.

Those predisposed to the formation of cerumen in the ear should be instructed to clear the ears of the same before bathing, as the sea water is apt, instead of disintegrating the ceruminous mass, to cause it to swell by absorption, and thus cause trouble.

Those suffering from acute middle ear disease or active chronic purulent affection should be prohibited from sea and river bathing altogether; this applies with even greater force to sufferers from any labyrinthine affection.

Patients with chronic catarrhal ear disease, while permitted to indulge in bathing, should be warned against too long continued stay in the water, and against too strenuous swimming and especially diving: instead of diving they may be advised to duck with the nostrils and ears obstructed with their thumbs and index fingers of the respective side. Those suffering with latent or periodic purulent otitis should have their ear or ears stuffed with plugs of absorbent cotton dipped in albolene or olive oil, and wear a closely fitting rubber cap over their ears, avoid diving or ducking, and always keep above water; immediately after bathing remove plugs and dry canal. Any appearance of pus or the least pain calls for immediate cessation of bathing and for medical advice. Those predisposed to furunculosis of the external canal should protect the canal with some borated vaseline or zinc oxide salve.

A danger which, though it may appear far fetched is nevertheless within the domain of the possible, is injury to the drum when the bather exposes his side to the onrushing wave, and the ear is thus struck sideways with considerable force. It is a well known fact that in a certain class of patients syringing of the ear, even with warm water (as it should properly be done), not to speak of cold, is apt to produce dizziness and even fainting, no matter how mild the force of the injected stream. It stands to reason that when a volume of cold water strikes the drum with sufficient force it is apt to produce dizziness and even unconsciousness, which may be followed by drowning.

1340 Madison Avenue.

FOOD COMBINATION.

By THOMAS J. ALLEN, M.D.,

EUREKA SPRINGS, ARK.

"Ninety per cent. of all human ailments, apart from disorders incident to old age and acute infections, are due to wrong combination and foolish food selection," says Dr. William H. Porter, Professor Emeritus of Medicine and Pathology in New York Post-Graduate Medical School and Hospital, in a recently published book, a conclusion based upon long experience in the treatment of chronic ailments.

"Certain foods, good in themselves, play havoc with the driving parts of the human machine when mixed," says C. K. Curtis, head of America's largest periodical publishing house, in an interview telling how he keeps fit for a big job.

A few years ago, a member of the Philadelphia County Medical Society, reported that he had discovered, in an investigation of the digestive ailments of children, that beef and milk are incompatible, as reported in the Medical Record at the time.

In a boarding school near Belfast, where I was pupil and teacher for eight years and where I made such progress in the study of physiology and the rudiments of medicine that I was able to secure a teacher's certificate in physiology, of South Kensington, London, before the age when such studies are usually begun, my interest in diet was stimulated by a copy-book headline which said that "Diet cures more than the doctor." I found that during the four years in which I had been fed the extremely simple ration of the pupil, there had not been a single death among nearly a hundred and practically no attention from the physician, whereas when I was promoted to the officers' table where the

forty-seven varieties were served, I suffered frequently from tonsillitis, and when we were visited by typhoid—which was promptly stopped by changing the water supply—myself, the assistant steward, who had recently left the ranks, and a girl who worked in the dining room and thus had access to the varieties, were the victims.

When the time came, rather late in life, as the custom goes, to feed a boy and a girl of my own, I had arrived at the conclusion that most diseases, chronic and acute, are fundamentally due to "wrong food combination and foolish food selection," as Dr. Porter, above quoted, put it; so I started them, after they had finished their scientific infant feeding, on a ration that allowed of no "foolish combination." After four years of this régime I am perfectly satisfied with the results. The photograph of the elder child has been published in a medical journal, reported by a professional friend as "simply perfect," both children were reported in the Federal inspection, "much above the average in physical and mental development"; and their photographs were shown in the September, 1920, issue of the *National Magazine* as members of "The Best Fed Family in America."

While connected with a Chicago medical school, in 1907, I conducted a series of experiments, laboratory and clinical, to determine the principles of compatibility of foods, which I had been studying for ten years. From this study the hypothesis of variation as the fundamental physical factor in cancer originated, to which I shall briefly refer again.

I mention these views and experiences by way of introduction to a subject not set down in the books. At the time my systemic study of compatibility began, I could find nothing on the subject in any published work, and only within the past year has my position been supported by a competent investigator.

Nearly ten years ago, the manual of instruction issued by the State Board of Health of Illinois on Tuberculosis advised that the sufferer from that disease, "Eat at a meal foods that digest in about the same length of time" (I quote from memory). This suggests the first rule for compatibility. Some foods, we know, are ready to pass out of the stomach in about an hour after ingestion while others require to remain for four or five hours ordinarily. An eminent English authority on diet, Sir Lauder Brunton, has carried this so far that, in a recently published work, he advises that, in certain cases, the yolk and white of egg be fed separately, the two requiring so very different systems of digestion.

As a rule, high protein foods (flesh, fish, beans, cheese) require much longer treatment in the stomach than the low protein class (rice, bread, fruits, vegetables). Accordingly, these should be, as far as possible, eaten separately. It has been generally understood that the potato forms a good combination with beef or other flesh food; because the potato is deficient in protein while rich in carbohydrate, which the other lacks; but, their modes of digestion are so different that they are quite incompatible, as Dr. Porter has determined. When I was engaged in sanatorium work, we had mutton or beef with bread on one day in the week, fish with bread on Fridays, but never potatoes with either; baked potato being furnished only with bread. Under this rule, milk is incompatible with flesh foods, contrary to the view of Dr. Porter, whose ideal meal is beef, bread, and milk. If it is well to reduce the intake of flesh in kidney ailments, in pregnancy, and in arteriosclerosis, it should be well to reduce it under any conditions almost. My objection to flesh foods is not that of the vegetarian but because of its extreme incompatibility with fruits, milk, potatoes, and green vegetables, with which it is commonly eaten indiscriminately. Although I have not eaten a pound of flesh food in fifteen years, I should unhesitatingly choose to live on bread and meat in preference to the average vegetarian's ration. The poor class of Ireland live well on potatoes and milk, with a much lower cancer rate than that of the Ulster counties where the diet differs little from ours. (The rate for Kerry county is 4, for Armagh, a prosperous Ulster manufacturing district, 13.)

Pavlov discovered that each food requires for its proper digestion its own special secretion. This suggests the rule for combination that, foods eaten at a given meal should be of a class. With few exceptions, animals are classified according to their feeding — carnivora, herbivora, frugivora, etc. True, then ultimate nutrients of all foods are the same, yet the lion would not fare well on grass nor the ox on flesh. The anthropoids, to which class man belongs, feed upon fruit exclusively (including nuts), their "canine" teeth being more prominent than those of man, in whom the original purpose of the prominent, sharp fangs, was defense. Inquiring at the Zoological Gardens in London and at the Bronx Park, New York, where several chimpanzees are usually kept, I secured the information that our nearest relative is scientifically fed upon bread and milk in winter and fruits in summer.

Fruits, for example, differ so much from flesh in their mode of digestion that they should under no circumstances be eaten at the same meal, as Dr. Porter suggests, they are best eaten exclusively for breakfast. Although there is considerable difference in the mode of digestion of cereals and milk, yet the fact that cereal has been found the best modifier for the infant's milk suggests that bread and milk are as nearly compatible as any two classes of foods, and experience confirms this. Nearly all of Metchnikoff's cases of extreme longevity had lived for the greater part of their lives on bread and milk.

Starch can digest only in an alkaline medium. Hence starches and acids are incompatible, tending to fermentation. Buttermilk is more easily digested than sweet milk, so I tried using freshly made buttermilk with brown bread for our children, but the combination caused so much fermentation that we had to give it up.

If these conclusions are correct—and ample laboratory and clinical investigation proves them to be correct—the results of the indiscriminate mixing of the great variety of foods commonly used even by the poorest to-day must be fraught with serious consequences. Careful examination of the statistics of cancer in all countries where reliable records are obtained, compared with the habits of eating of the respective peoples led to the adoption of the hypothesis that variation in feeding is the fundamental physical factor in cancer. This has been

established, well supported by the following consideration, briefly stated:

The cancer rate of Irish, German, and Scandinavian immigrants to America is more than doubled, while that of Italians, Greeks, Bohemians, Russians, and others who retain their former habits of eating, shows little change. Correspondingly, the rate of negroes in many northern cities is three times greater than that of the southern negro. This cannot be due to change in climate, clothing or any other habit except eating. .

The highest rates for occupations, in England and America (World's Statistics of Cancer, Hoffman), are, commercial traveler, inn keeper, hotel servant, midwife, schoolteacher, nurse, excluding, of course, chimney sweep. These are the classes who are most subjected to variation in feeding. Hoffman mentions that the rate in institutions for the infirm is much lower than the average, although he offers no reason, but suggests that we should naturally expect it to be otherwise. The ration in such institutions is much more uniform than the average.

The highest rates for cities are those of a few manufacturing suburbs in the eastern States and the larger cities of California. With fruit and vegetables constantly, fish and other flesh food more available, the greatest variation is possible in California.

Williams and other investigators have found that the rate of vegetarians is lower than that of those who live on a mixed diet; while the Eskimo, cannibals and the primitive Indians, living upon flesh exclusively, are immune. Flesh foods are more incompatible with other foods than all others within themselves.

Fish are more subject to cancer than any other animals, the trout (Bashford), the most voracious and various in food, being most so.

Bertillon reported to the French Government, on survey of the statistics of cancer, "Something in the diet."

Dr. William Mayo, as president of the American Medical Association, said, "bad food preparation," the body of the Association concurring, at San Francisco meeting. Food preparation is, essentially, food compounding, the primitive custom being, largely, the eating of one food at a time—monodiet.

The outstanding feature of cancer is premature senility which is also marked, commonly, by arterioclerosis. Bishop has found the single protein diet treatment to be effective in this.

Burbank tells me that he has concluded that cancer in plants is essentially the same as cancer in animals; and, he says, in his "Human Plant," "When a plant is fed a varying ration it is quickly attacked by fungoid diseases. On a wooded tract adjoining our city limits, on an Ozark hill, I have more than twenty cancers on trees under observation. I have never seen one on a pine, which grows only in a particular kind of soil, while they are most frequent on oaks, and most extensive on those growing on steep hillsides. Smith found daisies most subject among small plants. The daisy grows most commonly in meadows covered with manure. Oaks grow anywhere.

Experiments have proved that mice fed on whole rice develop cancer rarely, while those fed on a mixed ration develop implanted cancer readily and recover with difficulty.

In a recently published work, Dr. L. Duncan Bulkley, of the New York Cancer Hospital, perhaps our ablest practical authority on cancer, says: "The advance of transportation and facilities for cold storage have brought from far and near an innumerable number and variety of articles of food and drink . . . which bear no relation to the few simple articles formerly consumed . . . making the greatest departure from the simple life of aborigines, who are free from cancer."

Darwin says (Origin of Species, p. 43), that variation in feeding is the chief cause of variation in the lower forms, quoting Walsh, a distinguished American naturalist, to the same effect. Abrams quotes Von Leyden as saying that *Ochneria dispar*, which naturally feeds on oak leaves, produces albino progeny, when fed on other leaves, but returns to normal when its natural food is supplied.

Cancer is a reversion in cell growth, its inception stimulated, locally, by chronic irritation, when a precancerous condition of the blood is favorable to its development. Exactly what this condition is requires an immense amount of investigation, but beyond reasonable doubt variation in feeding is the largest factor in establishing it.

AUTOMATIC GRAVITY ANESTHETIZER.

By A. L. SORESI, M.D.,
NEW YORK.
VISITING SURGEON, GREENPOINT HOSPITAL.

THE automatic gravity anesthetizer, as its name indicates, delivers the anesthetic to the mask by gravity in any amount and combination desired, that can vary from a continuous abundant stream, to one or more drops per minute. The amount can be increased or decreased at will, or can be kept stationary for any length of time or stopped completely by simply turning a small knob. The apparatus will functionate with perfect satisfaction under all circumstances; climate, temperature, altitude, position of the patient, will not hamper the perfect work of the apparatus, because its construction is so simple that there is nothing to get out of order. It can be clamped to any table or bed, put at any height, and—by means of a ball-and-socket arrangement of its support—bent to any angle; so that the anesthetic is carried to the mask by the force of gravity which naturally, is absolutely constant under all circumstances.

The apparatus is very compact, solid, practically unbreakable, takes up so little space, that it could be carried in one's pocket. It consists of a metal cylinder lined with glass of about 250 c.c. capacity containing the anesthetic (Fig. 1 *C*); a little chamber through which the anesthetic drops (*C*); a tube (*T*) that carries the anesthetic to the mask (*M*); the whole apparatus is attached to the operating table or bed by a support (*s*) which can be raised or lowered and bent to any desired angle.

The *modus operandi* is extremely simple and easy; clamp apparatus to operating table or head of bed (Fig. 1 and 3); close valve (V) (Fig. 2, A and B) by turning handle (2) (Fig. 1 and 2)

toward (*O*) (Fig. 2, *D*); fill cylinder by unscrewing knob (1) (Fig. 2, A and B) and pouring the anesthetic on the top of the cylinder, which top has several holes, Fig. 2 and 3, and is made funnel-like in order to facilitate the filling of the cylinder

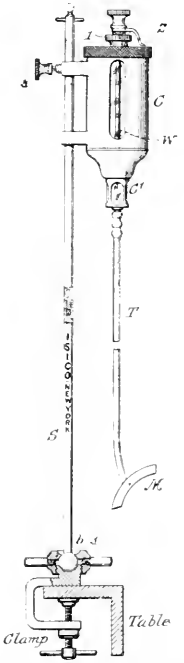

FIG. 1.—Complete automatic gravity anesthetizer. *C*, Container holding about 250 c.c.; *C'*, glass chamber through which dropping of anesthetic can be watched; *1*, knob opening holes that will allow filling of container *C*; *2*, handle that regulates opening of pin valve; *T*, tube to carry anesthetic to mask; *M*; *b.s.*, ball and socket joint allowing tilting of the apparatus when table is, for instance, in the Trendelenburg position; *S*, support holding apparatus, which can be lowered at will secured by screw.

and at the top has a small hole acting as a vent; this hole is covered with a small spring which is pushed aside when filling the container; foreign bodies such as pieces of cork, tin, etc., are prevented from entering the cylinder by a wire net (Fig. 2, A and B) put under the cover; when the cylinder is filled screw on knob (1) in order to prevent unnecessary evaporation of the anesthetic. The anesthetic is delivered to the mask by turning the handle (2) toward N, 1, 2, 3, etc. The turning the handle opens the pin valve (*V*) and allows the dropping of the anesthetic into the glass chamber (C') (Fig. 2, A); thence through the rubber tube to the mask. The amount of the anesthetic delivered to the mask can be watched and controlled by looking through the small glass chamber (C'). In all cases after the patient is well under, the flow of the anesthetic can be regulated, so that a certain amount is delivered to the mask and that amount is kept constant through the whole anesthesia, even if the cylinder should be refilled, because knobs (1) and (2) (Fig. 2, A and B) are independent of each other, so that the cylinder can be refilled without interruption, or changing the flow of the anesthetic to the mask.

When the surgeon wishes to give a mixture of ether and chloroform, for instance, this can be done in an ideal manner by using two of our containers (Fig. 2 E) one filled with ether, the other filled with chloroform, the two connected by a Y-tube, the two upper branches of the Y-tube being fitted one to each cylinder, and the lower branch carrying the mixture to the mask (Fig. 4); the amount of ether and chloroform is regulated with handle (*B*) of each cylinder, and will naturally be constant during the whole operation if so desired, or modified according to circumstances.

We have found most convenient to use a mask somewhat modified (Fig. 4); in the center of the mask there is a metal disc and a metal tube; the metal tube which is attached to the rubber tube coming from the apparatus is perforated all around its attachment to the metal disc; this arrangement

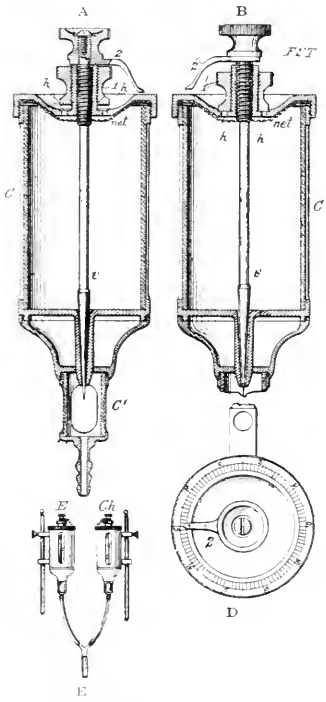

FIG. 2, A and B.—Sectional view of apparatus. *1*, Knob, raised in A to allow the filling of container, *C*, through holes, *h.h.*, closed in B to prevent useless evaporation; *F.S.T.*, funnel-shaped top allowing easy filling of container, *C*; *net*, wire net that prevents entrance of foreign bodies in container, *C*; *V*, pin valve regulated by handle, *2*, and opened in A, closed in B; *C*, container holding about 250 c.c.; *C'*, glass chamber; *D*, view of funnel-shaped top surrounded by numbers indicating the various openings of the valve, *2*, or closing of the same; *E*, two containers for the simultaneous administration of ether and chloroform; *E*, ether; *Ch*, chloroform, both flowing to the mask independently through Y-tube

allows a more even and expanded distribution of the anesthetic all over the gauze on the mask, instead of having the anesthetic drop always on the same one spot on the gauze. On the side of the mask there is also a small female screw; to this is

screwed the end of the tube containing ethyl-chloride, so that the anesthesia can be started with ethyl-chloride and continued with ether.

The advantages which the apparatus offers are; The administration of the anesthetic is even, continuous, requires a minimum of anesthetic—which for large hospitals means a great saving.

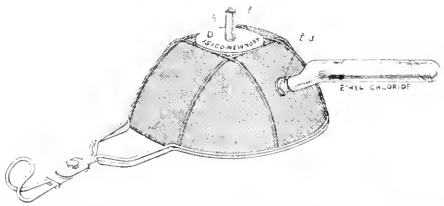

FIG. 4.—Mask that allows administration of ethyl chloride anesthesia, by screwing tube containing ethyl chloride to the mask, *t s*, and distributes the ether well over the mask by means of the holes, *h*, made in tube, *t*, that spread the ether over metal disk, *D*

The anesthetist is perfectly free, has no anesthetic bottle to hold nor valves to switch continuously, so that he can devote all his attention to the patient.

The anesthesia is so easy and smooth that the anesthetist does not get tired easily, and this is important, when there are many anesthesias to be administered in succession.

A smooth anesthesia is possible, even when the anethetist is not very competent, because once the flow of the anesthetic is regulated it will be constant for any length of time.

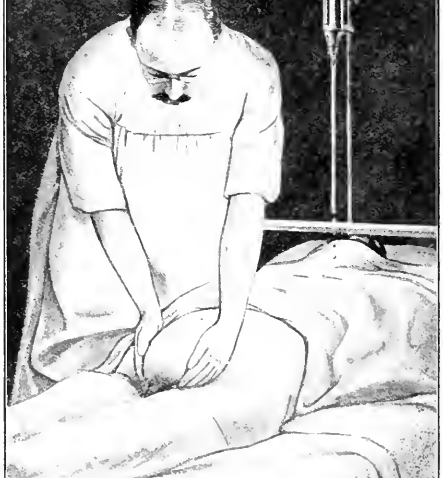

FIG. 3.—Apparatus attached to bed, for urgent obstetrical or other cases.

In emergency cases, such as obstetrical ones (Fig. 6), when the surgeon cannot get a competent anethetist immediately, as it happens in villages and small towns or at night and in emergencies, the surgeon can start the anesthesia and proceed with the operation all alone, or with the help of anybody who can, according to orders, turn the little handle that regulates the opening of the valve.

The same apparatus is equally efficient for both chloroform and ether, is compact, small, practically unbreakable, not expensive, and always ready to be used under all conditions and circumstances.

LARGE DOSES OF BACTERIAL VACCINE IN GONORRHEAL ARTHRITIS.

BY H. W. LYDING, M.D.,
NEW YORK

THE case herewith reported is of interest because the persistent and continued use of a combined vaccine was able to effect complete cure of a severe gonorrheal arthritis and because the patient was able to tolerate, without serious constitutional effect, doses which were very much larger than those ordinarily given. It was necessary to raise the dosage in order to eradicate the infection.

W. S. G., male, thirty-two years old. Gonorrhea of two years' standing. Had received specific treatment immediately after infection, but the condition nevertheless became chronic and did not respond to the usual measures employed. Gonorrheal discharge continued and was present September 10, 1920, when the patient came under the writer's care. He complained of intense pains throughout the lumbar regions, the perineum, the thighs, and the testicles. He received an injection into the gluteal muscles of one mil of the following bacterial vaccine: gonococci, 2,000,000,000; streptococci, 100,000,000; pneumococci, 100,000,000; colon bacillus, 200,000,000; pseudodiphtheria bacilli, 300,000,000; white staphylococci, 1,000,000,000. September 15 another intramuscular injection of one mil; September 22, two mils; October 1, two mils; October 15, three mils; November 15, three mils; November 22, five mils; December 15, four mils.

The arthritis appeared to improve after the first few injections, so that the patient did not return to the office for two weeks after October 1. He then came back and asked for resumption of vaccine therapy because of renewed pains. There was an interval of one month before he again came for treatment. He was then given five mils of this vaccine, whereupon the urethral discharge completely stopped and has not returned since. The final dose on December 15 was followed by cessation of the pains, which up to this date (April 1, 1921), have not returned.

The only systemic reaction which the patient felt was, after the injection of five mils, a moderate chill lasting about thirty minutes. The other injections caused no unpleasant effects whatever. On the basis of this and other experiences I have no hesitancy in using very much larger doses of bacterial vaccines than those recommended by manufacturers In acute cases it is my practice to begin immediately with heavy doses. My rule is: The higher the temperature the larger the dose, since experience has shown that injections of vaccines have a remarkable anti-febrile effect, if they are given early. As to the theory that bacterial vaccines in acute infections may do harm by adding toxic materials to an already intoxicated system, it does not hold good in practice, since injections under these conditions are followed by a drop of temperature rather than by a rise. The fact seems to be that it is not the bacteria which are so toxic, but rather the products of their life activity, so that killed bacteria can be injected in large quantities

without fear of toxicity. In very old chronic infections in which the system has apparently become tolerant to the bacteria, I often find it necessary to work up gradually to what appears to be very large doses, in order to arouse a sufficient immunizing reaction on the part of the system to effect a complete cure.

As to the objection that the use of a combined vaccine, undoubtedly containing bacteria which are not represented in the infection, is unscientific, I am quite in accord with the recent view expressed by Almroth E. Wright (*The Lancet*, March 29, 1919), that "there may exist a useful sphere of application for collateral immunization; and that such sphere may, perhaps, be found in those cases where the infection is of very long standing, and where the patient has become very sensitive to, and has probably come very near the end of his tether in the matter of immunizing response to the particular species or strain of microbe with which he is infected."

236 WEST 15TH STREET.

Medicolegal Notes.

Privileged Communications to Physicians Not Admitted in Action on Accident Policy.—An insured under an accident policy, on the day following his moving a heavy ice box on a neighbor's premises, was attacked by a pain in the side and shortly afterward was attended by physicians, was taken to a hospital and there operated upon. In an action on the policy after his death, some time later, the medical testimony showed that prior to being sent to the hospital the diagnosis of some of the physicians was that there was an infection of the gall bladder. The operation disclosed, however, that a part of the omentum had become gangrenous to an extent about the size of a man's palm. This portion was removed, but subsequently there developed a paralysis of the muscles in the walls of the intestines, and a secondary operation was performed. The distension of the bowels caused by this paralysis increased, and he died as a result thereof six days after the first operation. The testimony indicated that this condition of the membrane was probably produced by a twisting as the result of some violent physical strain on or of the patient's body. Under the testimony received by the court under its first ruling there was evidence that the deceased had at several times, but more than two days after the accident, stated to the attending physicians who were then treating him professionally, that he had twisted himself at the time he was moving the ice box, and that he attributed the subsequent pain to such twisting. The physicians further testified that considering what was disclosed at the operations and the autopsy, taken in connection with the statements that the deceased made to them as to the moving of the ice box, they ascribed the cause of his death as being traceable to such injury. A motion was made by the defendant to strike out the testimony of the physicians, which was granted, and thereupon the defendant moved for a directed verdict in its favor, which the trial court granted "solely upon the ground that the only evidence of the accident, which is claimed was the proximate cause of the deceased's death, is the statements of the physicians and surgeons who were called to treat him and to operate upon him, and, the court being of opinion that such testimony was incompetent because of the privilege under section 4075 of our (the Wisconsin) statutes, there is no evidence to sustain the claim of the plaintiff to the effect that there was an accident within the meaning of the terms of the policy." In affirming this judgment, the Wisconsin Supreme Court holds that, while the patient may waive this privilege, there was no express waiver by him in this instance, and it cannot be waived by the administrators, executors or personal representatives of the deceased, nor by any person standing in the position toward deceased as did the plaintiff beneficiary in this case (the widow of deceased). It was unsuccessfully urged by the plaintiff largely from the standpoint of the probable injustice that would otherwise result in this instance, as well as in similar situations, that under the facts in this case there was intended by the insured that there should be a waiver of such privilege from his taking out such an accident policy, in that the very nature of the contract implied that it was anticipated that in case of accident the testimony of physicians or surgeons would be required in order to establish a right to recover, either for the insured himself in case of an injury not resulting in his death, or for the designated beneficiary in case such injury resulted in death, and that the contract of insurance, expressly providing for the furnishing of proofs of death necessarily required the statements or evidence of physicians. It was held that the trial court was right in ruling that the information obtained by the medical witnesses while attending, prescribing for and operating upon the patient, were excluded by the statute. Another ground of exclusion was stated by the court. The testimony of the physicians in this case on all the other points on which it was offered would, the court said, have been of no avail and weight, unless there could have been connected with such testimony the declarations of the deceased made some days subsequent to the accident to these same physicians that he did injure himself by the moving of the ice box. Such declarations were held no part of the res gestæ, were hearsay and inadmissible.

Recitals of past events made by an interested person are no more admissible because made to physicians or surgeons, even when necessarily so made for the purpose of proper treatment by such, than if made to other persons. Justices Owen and Liebecker dissented on the ground that by the very act of applying and paying for an insurance policy of this nature the insured thereby waives the privilege of the statute just as effectually as does the testator who calls upon his attorney to witness his will; and that there was ample evidence from which the bodily injuries might be inferred without reliance upon statements made to the physician by the deceased.—Maine v. Maryland Casualty Co., Wisconsin Supreme Court, 178 N. W. 749.

Negligence in Diagnosis and Treatment and Cause of Death Held for Jury.—The Minnesota Supreme Court holds that a physician does not insure either correct diagnosis or correct treatment, but he is required to possess the skill and learning which is possessed by the average member of his school of the profession in good standing in his locality and to apply that skill and learning with reasonable care. If he fails in this, he is negligent and may be held liable for injury resulting therefrom. Defendant diagnosed a case of diphtheria as quinsy, and on two occasions lanced the patient's throat. The patient died soon thereafter. It was held (two judges dissenting) that under the evidence the question of the defendant's negligence in diagnosis and treatment and the question whether such negligence caused the death should have been submitted to the jury, and a judgment on a directed verdict for the defendant was reversed.—Clark v. George (Minn.), 180 N. W. 1011.

Evidence as to Physician's Attendance Under Indemnity Policy.—In a claim under an accident and sickness policy providing for a payment for total disability should the insured be confined within his house by disease and "therein regularly attended by a qualified physician," the evidence was conclusive as to the disease, but uncertain as to the necessary confinement to the house. As to the requirement of attendance by a physician therein the evidence showed that during the period claimed for, the plaintiff was never attended at the place of confinement by a qualified physician, but merely communicated through members of his family with his physician over a telephone, and that subsequent to a period of two weeks, during which he testified he was confined to his house, he visited his physician on an average of twice a week during the term of his disability. The Appellate Division holds that this evidence failed to establish one of the necessary requirements to recover under the policy, namely, that he was regularly attended by a qualified physician during his illness.—Campana v. Ridgely Protective Assn., 186 N. Y. Supp. 82.

SIMULTANEOUS DISLOCATION OF BOTH CLAVICLES.

STRANGE as it may appear at first sight, simultaneous dislocation of both clavicles has not a bad prognosis. It must be recalled that reduction cannot always be obtained; sometimes the displacement can be corrected, but it is impossible to maintain the reduction. Finally it is often a difficult matter to effect a cure without deformity. Therefore the patient should be warned at the onset of treatment that he will recover with some deformity and thus a future malpractice suit will be avoided. In one reported case the clavicles rested on the edge of the sternum, behind the sternal insertion of the sternomastoid muscle; in most all the other reported cases the deformity was marked, although in many the final functional results left nothing to be desired. The resulting deformity, although not inconvenient for males, is very distressing for women from the esthetic viewpoint.

From the viewpoint of function, what is the prognosis of simultaneous dislocation of both clavicles? The importance of this question can readily be conceived, especially at the present time when legislation on liability brings up constantly important medical questions. In a general way it is known that the functional prognosis of dislocation of the clavicle is regarded as good, but in this respect there is, nevertheless, no absolute and fixed rule. As to simultaneous dislocation of both clavicles, the relatively small number of reported cases does not permit one to formulate strict conclusions, but it appears to us, however, that the prognosis can, in a general way, be regarded as favorable. Certain reserve should be maintained in certain circumstances, and although some severe double dislocations have been recovered from nicely, so far as function is concerned, there are other instances in which the return of strength in the parts has been far from complete. In a recently reported case of simultaneous dislocation of the clavicles in all four of their joints a functional impotency resulted, which, for a laborer, was a serious infirmity.

A positive diagnosis is usually made without difficulty, but it may happen that one of the dislocations is overlooked. In the case of acromioclavicular dislocation the diagnosis is based upon the projection of the external end of the clavicle, the deformity of the stump of the shoulder, the existing acromioclavicular depression and abnormal mobility of the clavicle. In sternoclavicular dislocation, the deformity and abnormal mobility are the two important diagnostic signs, and should any doubt exist in either case the *x*-rays would settle the question. The differential diagnosis in simultaneous dislocation of the clavicles must evidently be made in each kind of dislocation. In cases of acromioclavicular dislocation it will usually be enough to seize the clavicle at its middle and detect its mobility. To differentiate this lesion with a dislocated shoulder, the movements of the arm are preserved in the former and the tumefaction over the shoulder is formed by this external end of the clavicle resting on the acromion. Fracture of the acromion causes the acromial apophysis to project, or there is a depression over the line of fracture. It must be recalled that fracture of the acromion has been known to occur at the same time as acromioclavicular dislocation. Dislocation of the outer end of the clavicle may be mistaken for a fracture of this bone, but in the former lesion the pain will be found to be seated directly over the acromioclavicular joint, while in fracture the pain is just to the inner side of the joint. In dislocation, reduction is usually easy, while in fracture the outer end of the clavicle is often only incompletely reduced. A differential diagnosis of sternoclavicular dislocation may perhaps have to be made with exostosis, which requires no comment, while in cases of fracture of the bone the deformity will be seated at a notable distance from the midline of the sternum and crepitation will be distinct. Finally, ecchymosis is almost invariably present in fracture and is often wanting in dislocation.

RHEUMATISMAL CONJUNCTIVITIS.

THIS ocular manifestation of acute and chronic articular rheumatism in most instances assumes the aspect of simple conjunctivitis with edema. The lids are swollen, the eye red and injected, with lacrymation, characterized by a flow of clear, transparent fluid containing a few filaments of mucus. Occasionally the secretion may be mucopurulent. The patient complains of a pricking sensation as if sand were under the lids, but in some cases the pain may be so sharp that it is compared to pain in the joints. Examination shows the palpebral and bulbar conjunctivæ are very red, the vessels are dilated and flexuous, while the submucous edema is sometimes very pronounced, producing an intense chemosis encroaching on the cornea, giving the latter an unpolished appearance. In the vast majority of cases the conjunctivitis of acute articular rheumatism certainly resembles the catarrhal type of the process.

The conjunctivitis and the joint manifestations may alternate or coincide, undergoing the same evolution and the same clinical variations. Some observers have described other types of rheumatismal ocular inflammatory processes, as for example, a follicular or dry catarrhal conjunctivitis characterized by a slight redness of the lids which appear to be heavy, and close in spite of the patient when he works with artificial light. He will complain of a pricking sensation and impeded movement of the lids, as well as a sensation of sand between the bulbar and palpebral conjunctivæ. The lids are stuck together in the morning. Examination shows the palpebral conjunctiva dull, injected, red, uneven, and puffed on account of hypertrophy of the papillary bodies. The bulbar conjunctiva is only slightly injected, the cornea is intact. The lacrymal and conjunctival secretions are slight. An eczematous rheumatismal conjunctivitis has likewise been described, as well as a form closely resembling the gonococcal variety, but the rheumatismal origin of the latter is more than questionable. As to the follicular variety it is rather an attenuated form of rheumatic catarrhal conjunctivitis, while the so-called eczematous variety depends upon the lesions of eczema, that will at the same time be found on other parts of the skin, rather than on the rheumatism itself.

To make a differential diagnosis of this ocular localization of rheumatism the personal and hereditary antecedents of the patient should be taken as a basis. But this is not enough, because a subject with rheumatism may develop an ordinary acute catarrhal conjunctivitis, so that in order to make a sure diagnosis the patient must have recently presented or be actually suffering from rheumatismal manifestations. The patient will have suffered from some joint pains and these having passed off a conjunctivitis develops, or the two morbid phenomena coexist. Therefore the alternation or coincidence of the conjunctivitis with the joint manifestation should lead to the correct diagnosis. The manner of the onset of the affection, its evolution, duration, and the effect of treatment are likewise to be taken into consideration. Pain, often severe, occurs in rheumatic conjunctivitis and is almost absent in ordinary catarrhal conjunctivitis. The rheumatic form of the affection presents an astonishing mobility, it frequently recurs, and its duration is sometimes long, far more so than acute catarrhal conjunctivitis. Occasionally, however, complications in other membranes of the eye may ensue, such as exudative iritis, but these cases are uncommon and usually the process undergoes its evolution without complications, and recovery ultimately takes place.

Treatment for the rheumatism itself will usually bring about an amelioration and cure of the ocular process, but with the general treatment with large doses of the salicylate some local treatment should be adopted, avoiding any irritating drug. Warm boiled water or a warm boric acid solution applied on compresses will usually suffice, if necessary combined with instillations of a cocaine solution; or a very mild solution of zinc sulphate, one grain to the ounce, may hasten the cure.

BACTERIOLYTIC VIRUS.

In 1917 Herelle made the discovery that a filtrate from the stools of dysenteric patients, especially during convalescence, could kill and dissolve suspensions of dysentery bacilli. Of much interest *per se* this phenomenon also opened up other fields of research. This property could be made to pass indefinitely from one suspension of bacilli to another. In other words, an invisible filtrable virus was found to be able to reproduce itself, and it was proved later that this property was not restricted to dysentery bacilli. From stools of typhoid fever patients similar bacteriolytic filtrates could be obtained, and this proved also to be the case with fowls attacked with so-called fowl typhus. Bacteriolytic bodies have also been shown to exist in normal stools. That a living organism was responsible for this property was not necessarily implied, for the presence of an enzymic catalysator might also explain the behavior. However, with the progress of the investigation, the majority of observers, including Herelle himself, adhered to the belief in a living cause of the phenomenon in question. It was found that the intestine is not necessary for the production of the phenomenon, for an injection of colon bacilli into the peritoneal cavity will give rise to a filtrable bacteriolytic substance. This Bordet phenomenon may not, of course, be identical throughout with the Herelle discovery. The assumption is that the bacilli contain the active substance preformed or that it is formed by a lytic process, although an explanation of this sort does not seem to explain the power of the bacteriolytic substance to perpetuate itself.

Professor Bail of the Hygienic Institute of Prague University takes up this subject in the *Wiener klinische Wochenschrift* for May 19, 1921, xxxiv, 20. He imagines that the defensive forces of the body may be able to break the bacteria into fragments so small that some of them can go through the Chamberland filter. The fragments constitute living organisms which have become greatly altered biologically. Their ability to proliferate explains the perpetuation of the unknown virus. The author compares the formation of this new generation with the ordinary process of sporulation. To a certain extent the new individuals must resemble spores, but we do not know yet that the fragments of the bacilli can develop, like spores, to mature individuals. That they share this property, however, seems quite likely, although under conditions which are evidently absent in the phenomena discovered by Herelle. For further advances along this line of study we must await the success of attempts to culture the new

individuals. Comparison with the results of studies by Weil and Felix on mutations of the Proteus throws some new light on the subject. The fragmented bacilli do not seem able to proliferate in the body to the degree seen in the filtrates. Thus far there is indicated the possibility that the Herelle discovery may throw light on the causation of certain diseases, as typhus, scarlatina, and swine plague, through the operation of mutants of known germs.

Passage of the Anti-Beer Bill.

The House of Representatives in Washington has passed by a vote of 250 to 93 the Willis-Campbell bill absolutely prohibiting the therapeutic use of beer, and probably before this issue of the Medical Record is printed the Senate also will have passed the same measure. If the bill only prohibited the medicinal use of beer, most men, physicians and laymen, would shrug their shoulders over this one further step in the Prussianizing of a once free country and let it go at that. But it is no doubt merely an emergency measure intended to head off the brewers from putting out any beer until the new and more drastic Volstead bill, known as H. R. 6752, can be passed. According to this bill, as pointed out by the Committee on Industrial Alcohol of the American Chemical Society, any chemical or other manufacturing industry, using or depending upon alcohol could be shut down within thirty days. And no appeal could be made to the courts. Another section of the proposed new law would require the posting of permits for twenty days, before this basic chemical for many industries could be secured. Power is also given to compel the posting of a copy of the application upon the factory or business house. Then any one of a group of local, State, or national officials may file a protest to it. By the time the red tape involved was unsnarled, any reputable concern might be in the hands of the sheriff or the federal courts in a bankruptcy proceeding. We are very glad the father of this bill was simple enough to introduce it, for it has awakened the chemical industries to a realization of the danger to which the country is exposed by this fanatical legislation. So long as it was only the practice of medicine that was assailed the chemists and others took no interest in the measure, agreeing with the Committee on Industrial Alcohol of the American Chemical Society that "no substantial objection could be offered against it." But Mr. Volstead was unwise enough to touch the pocket nerve and the reaction is prompt and more or less violent. We hope he will go on in his attempt to cripple other industries; then perhaps the reaction will be so violent as to help even the practice of medicine.

Why Practice When Commissions Are So Good?

In the course of a long and varied medical career one receives much graft in the way of samples of drugs, foods, and apparatus, not to mention deeds of burial plots, certificates entitling the bearer to free cremation, and the like; but cash offers are few, hence our readers may be interested to learn of opportunities in that line. The following are extracts from a couple of circulars sent not long since to a number of practitioners in this city. The first one reads: "Inclosed find circular of our place. I would like to have you send patients here who are recuperating and also who are on diets, for I give the best care to any order given them by you. We have had many patients from other doctors and they were very much pleased with the place. We take special care of diabetic cases. I am sure your patients will like it here, as I'll give them every attention needed. . . . I will mail you a check for $5 for every patient sent, and you are welcome to come and see the place at any time without charge." The second offer is much more generous. The enterprising director of the institution writes: "We can increase your practice $2,000 a year in a perfectly ethical way and without any investment. Frequently, when a doctor fails to promptly benefit a patient suffering from neurasthenia, obesity, arterial hypertension, etc., they drift away and go the rounds of various systems, spending large sums and, as a rule, obtaining little or no relief. If you will permit us, we will explain how we propose to help you retain such patients. . . . You may have, in the rush of work, neglected to consider how grateful, in many instances, your patients would have been to you for supplying them promptly with special treatment of this kind. . . . In order to insure their faithful and regular attendance, which is generally difficult for the physician to obtain, all patients referred by you for treatment here are required to pay in advance for a course of one month or more, according to their needs and your advice. *We forward to you at once* $40 *to* $60 *for each patient*, in consideration of your advice and guidance in the treatment of the case. Patients are referred to you at stated intervals for medical examinations. Doctor, the ——— depends for its continued success and for the patronage of physicians upon its ability to produce successful results in treatment and upon its conscientious cooperation with physicians. It's worth investigating!" We should say so.

News of the Week.

Disease Spreading in Russia.—A *Central News* despatch from Helsingfors reports that Health Commissioner Samasjko announced before the Pan-Russian Health Congress in Moscow, on June 21, that cholera was raging in the southern and middle provinces of Russia, and that there was hardly a port of Russia free from malaria. The spread of these diseases is believed to be due, in part at least, to enormous swarms of gnats and flies.

League of Nations Faces Health Work Dilemma.—According to a report by the *Associated Press* the Council of the League of Nations, in session in Geneva, is struggling to solve a complication brought about by the abstention of the United States from participation in the health organization of the league. This problem is how to avoid duplication of the league's international work in hygiene with the work of the International Health Office, in which the United States is represented. The idea of the assembly is that international health work should be brought entirely under the

direction of one organization. A new provisional committee has been appointed which is to endeavor to secure unofficial representation in the International Health Office so that at least a working arrangement with the league can be effected.

Medical School Closes Doors.—Upon the one hundred and sixteenth commencement day of Bowdoin College, the Bowdoin Medical School closed its doors after an existence of more than one hundred years. This is because the college officials feel that they are able no longer to maintain the medical school in Class A with the financial support available. The degree of Doctor of Medicine was conferred upon only eight students.

Illinois Doctors Protest Against Dry Law.—Following the passage by the Illinois House of Representatives of the Anti-Saloon League's dry bill, which is much more drastic than the Volstead law, and would abolish medicinal beer, light wines, and other intoxicants, and permit the prescription of whiskey only, protests from Illinois physicians are pouring in requesting Governor Small to veto the bill. One thousand letters opposing the bill have been received in answer to a query sent out to ascertain the feeling of doctors in regard to the bill, and it is said that there are 4,000 additional protests in Chicago. It is reported that there is a movement on foot to form a union of Illinois physicians who object to the restriction on prescription privileges as contained in the prohibition bill.

The Willis-Campbell Bill Passes the House.—The "Anti-beer measure," carrying more stringent restrictions than the present Volstead law, passed the House of Representatives on June 27, by a vote of 250 to 93. This measure absolutely prohibits the prescription of beer as medicine, which Attorney-General Palmer ruled was permissible under the Volstead law. In addition to prohibiting medicinal beer, it gives the prohibition commissioner power to limit whiskey prescriptions to 100 every ninety days, and to stop the importation of any intoxicating liquors until the supply in this country held under Government supervision for non-beverage uses is exhausted. Representative Gallivan of Massachusetts, who vigorously opposed the measure, compared it to legislation in the time of Rameses I, when physicians were regulated by laws that compelled them to prescribe according to statute. If they adopted any treatment of their own they were put to death. As a result of this type of medical practice act, Representative Gallivan pointed to the one conspicuous relic of medical skill in Egypt, the mummy.

Doctors Consider Reduction of Fees.—In addressing the graduating class of the Detroit College of Medicine and Surgery on June 17, Dr. J. B. Kennedy announced that Detroit and Michigan physicians were planning to come to an agreement on easier fees for the sick. A committee has been appointed to study the question and to submit a report in a short time.

Pennsylvania Denies License to Minnesota Doctor.—Judge William M. Hargest of the Dauphin County Court, Harrisburg, has refused a writ of mandamus to compel the State Bureau of Medical Education to issue to Dr. Samuel S. Houlton a license to practise medicine in Pennsylvania, on the ground that being licensed by Maryland and Minnesota he should receive the same privilege for Pennsylvania under reciprocal relations.

The Right to Practice Surgery in a Hospital.—The Circuit Court for Talbot County, Md., has overruled the demurrer of the authorities of the Emergency Hospital of Easton growing out of the institution's action in having barred Dr. James A. Stevens from surgical practice in the hospital. The opinion, signed by Judges Hopper and Wickes, holds that under the by-laws of the institution the complainant "would have the management of his private patients and the right to perform surgical operations, subject in the latter instance to the consent of the active staff; that consent signifying that the operation was necessary or advisable, and not requiring the staff's consent to the surgeon selected by the patient to perform the operation. The office of the staff in this respect is specifically confined to deciding whether there should or should not be an operation. The resolution under question states who should compose the surgical staff of the hospital and places the complainant on the medical staff, thereby eliminating him from the surgical practice in the hospital. This the staff could not do, so far as the complainant's private patients were concerned, because the constitution and by-laws confer no such authority."

Work for Zionist Medical College Begun.—The American Jewish physicians have opened offices at 1225 Broadway, New York City, to begin the fulfillment of the promise made to Dr. Albert Einstein on his recent visit to this country, that the Medical Profession of the United States would contribute a fully equipped medical college to Palestine. This central committee will have charge of organizing sub-committees all over the country.

Annual Meeting of the Medical Library Association.—The twenty-fourth annual meeting of the Medical Library Association, whose membership includes all of the larger medical libraries of the country, and a large number of individual members, consisting of those interested in furthering medical library work, was held in Boston June 6, 7, and 8, 1921. The business meetings of the Association were held in the Boston Medical Library. In addition to the address of the president the program contained the report of a committee on standard Classification, and the system used in the Boston Medical Library, and this as explained by the chairman, Mr. James F. Ballard, was adopted, as being the most practical solution for meeting the perplexing problems of classification. This was followed by a discussion on reference aids, which was opened by Mrs. Grace W. Myers of the Treadwell Library of the Massachusetts General Hospital. An evening meeting, which was largely attended, was addressed by the president, Dr. John W. Farlow of the Boston Medical Library. This was followed by an interesting paper, illustrated by lantern slides, by Dr. George S. Huntington of New York City, entitled "Some historical facts concerning the catoptron of Johannes Remmelinus, and the superimposed anatomical plates during the early part of the 17th century." Following this Dr. Malcolm Storer of Boston, read a paper entitled "Interesting medical medals." In addition to the regular program visits were made to the various libraries in Boston. In each case the members of the Association were shown over the buildings and the

various points of interest were explained. Visits were made to the Harvard Medical School Library, Boston Public Library, Harvard College Library, Treadwell Library, and the Boston Anthenæum Library. Of particular interest was an exhibit of rare medical items from the library of Dr. Edward C. Streeter of Boston, spread in the exhibition room of the Boston Public Library. The exhibit was specifically epidemiological, the essential literature on fevers from Hippocrates to Lancisi, with a few sections such as Pleague, Syphilis, Venesection superadded. The permanent headquarters of the Medical Library Association are in the Medical and Chirurgical Faculty Building, 1211 Cathedral Street, Baltimore, Maryland.

Hospitals for Soldiers Approved.—Seven hospital projects recommended by the Board of Consultants on Hospitalization, for the treatment of former soldiers, have been approved by Secretary of the Treasury Mellon. They involve the expenditure of $3,101,000, which will be taken from the special appropriation of $18,000,000 for this purpose. An expenditure of $850,000 has been authorized for the addition of 250 beds and the improvement of existing facilities at the United States Public Health Service Hospital at Fort Bayard, N. M. The United States Public Health Hospital at Perryville, Md., is to be the site of a new hospital. A great deal of construction was done at this point during the war and additions will be made to accommodate 300 neuropsychiatric patients, at a cost of $500,000. At Ft. Logan A. Roots, Little Rock, Ark., provision will be made for a hospital for the treatment of 300 neuropsychiatric patients, at an estimated cost of $250,000. The tuberculosis unit at Lake City, Fla., the general hospitals at Fort Walla Walla, Whipple Barracks, Prescott, Ariz., and Alexandria, La., are also included in the list of hospitals to be expanded and improved.

Municipal Hospitals in Class A.—According to the report of Commissioner Bird S. Coler of the Department of Public Welfare recently submitted to the Mayor, the municipal hospitals of New York City have been increased in efficiency until they have all been rated in Class A by the American College of Surgeons. The report asserts that the higher standards were brought about by a program which brought all the hospitals of the department under the supervision of a general medical superintendent and by a policy of monthly conferences of the attending physicians of the several hospitals. To facilitate these conferences the methods of keeping records have been greatly improved. Commissioner Coler also claims credit for having improved the conditions surrounding the nursing service in these hospitals so that they have been enabled to attract more young women to take up nursing as a profession.

Hospital for Speech Defects.—The New York Clinic for Speech Defects, started three years ago, has obtained authority from Albany to change its name to the National Hospital for Speech Disorders. This was a preliminary to a campaign to raise $1,000,000 as a building and endowment fund for a hospital which is to be national in scope. The plan is to make the new hospital a training center for specialists in this field as well as a thoroughly equipped hospital for the treatment of all speech disorders. The hospital is to be a combination of school, clinic, hospital, and social center, combining reeducation and social service with medical and psychological treatment. It is the only institution of its kind in this country.

Cancer Hospital Plans Expansion.—The Memorial Hospital, New York, has prepared a definite program for enlarging its accommodations which is contingent upon the raising of a fund of $2,000,000. In initiating a campaign to raise this sum the hospital authorities point out that at present not more than one-sixth of the patients applying for treatment can be accommodated and that the teaching function of the hospital is also much restricted because of lack of room to care for the many patients applying for admission.

Broad Street Hospital to Be Enlarged.—A movement is under way looking to the organization of the Downtown Hospital Organization which will have for its object the development of the Broad Street Hospital into an institution with as wide a scope as any hospital in the world. A meeting is to be held on June 28 in the Chamber of Commerce, at which time officers will be elected and committees appointed. Steps will be taken immediately to enlarge the capacity of the hospital from 100 to 180 beds and to provide quarters for nurses in training.

Rhode Island Medical Society Receives Donation.—At the annual meeting of the Rhode Island Medical Society held in Providence on June 2, Dr. Edward M. Harris of Providence turned over a check for $5,000 to the society. This fund is to be divided, $3,000 going toward an endowment fund and $2,000 toward the printing expenses of the society.

The New York Diagnostic Society announces the following Prize Essay awards for the 1920 contest; Subject; "Group Diagnosis": 1st Prize, $300 to Dr. F. Thompson Leys; 2nd Prize, $150 to Dr Clinton Lake Potter; 3rd Prize, $50 to Dr. Homer E. Smith. Sixty-one essays were submitted.

Dr. Livingston Farrand, chairman of the Central Committee of the American Red Cross, has been elected president of Cornell University to succeed Dr. Jacob Gould Schurman who has resigned after a service of twenty-eight years. Dr. Farrand was for a number of years executive secretary of the National Association for the Study and Prevention of Tuberculosis.

Dr. George M. Piersol has resigned the professorship of anatomy at the University of Pennsylvania which he has held for thirty years.

Dr. Alonzo E. Taylor has resigned from the faculty of the University of Pennsylvania to go to the University of California to conduct special research work on the subject of nutrition.

Dr. A. F. Thomas has been appointed city physician of Newburyport, Mass., to succeed the late Dr. George D. McGauran.

Dr. Harold Gifford of Omaha has been given the honorary degree of Doctor of Laws by the University of Nebraska. This is the first time this degree has been conferred upon a member of the medical profession by the university.

Vacancy for Pathologist.—The Civil Service Commission of the State of New York announces an examination for the position of pathologist, first assistant grade, State Hospitals for the Insane, at

a salary of $2,700 to $3,300. Candidates must be licensed physicians who have had at least four years of experience in an approved pathological laboratory, two years of which must have been spent in the laboratory of a State Hospital or institution. The examination is open to non-residents. Application forms will not be sent out by mail after July 5 and may not be accepted after July 7. Application forms may be had by addressing the State Civil Service Commission, Albany, N. Y.

Society Elections.—THE AMERICAN PEDIATRIC SOCIETY, at its thirty-third annual meeting held at Swampscott, Mass., June 2-4, 1921, elected the following officers for the ensuing year: *President*, Dr. Maynard Ladd, Boston; *Vice-President*, Dr. Percival J. Eaton, Pittsburgh, Pa.; *Secretary and Treasurer*, Dr. Howard C. Carpenter, Philadelphia, Pa.; *Editor and Recorder*, Dr. Joseph Brennemann, Chicago.

THE AMERICAN MEDICAL EDITORS' ASSOCIATION, at its fifty-second annual meeting held in Boston May 6 and 7, 1921, the following officers were elected for the ensuing year: *President*, Dr. Frank C. Lewis, New York; *Vice-Presidents*, Dr. F. H. McMechan, Avon Lake, Ohio; Dr. D. S. Fairchild, Clinton, Ia.; *Secretary and Treasurer*, Dr. Joseph J. MacDonald, Jr.; *Executive Committee*, Dr. H. E. Lewis, Dr. H. S. Baketel, and Dr. T. L. Stedman, New York, and Dr C. C. Taylor, Philadelphia.

THE ILLINOIS STATE MEDICAL SOCIETY, at its seventy-first annual meeting held in Springfield, May 19, 1921, elected the following officers for the ensuing year: *President*, Dr. E. P. Sloan of Bloomington; *First Vice-President*, Dr. Archie W. Barker, Springfield; *Second Vice-President*, Dr. Henry J. Way, Chicago; *Secretary*, Dr. Wilbur H. Gilmore, Mt. Vernon; *Treasurer*, Dr. Andrew J. Markley, Belvedere.

THE NEW HAMPSHIRE STATE MEDICAL SOCIETY, at its one hundred and thirtieth convention held in Concord, May 25, 1921, elected the following officers for the ensuing year: *President*, Dr. Charles F. Walker, Keene; *Vice-President*, Dr. H. L. Smith, Nashua; *Secretary and Treasurer*, Dr. D. E. Sullivan, Concord.

THE MICHIGAN STATE MEDICAL SOCIETY, at its annual meeting held in Bay City, May 26, 1921, elected the following officers for the ensuing year: *President*, Dr. W. J. Kay, Lapeer; *First Vice-President*, Dr. J. W. Hauxhurst; *Second Vice-President*, Dr. Dent E. Sawbridge, Stephenson; *Third Vice-President*, Dr. Harlan McCullen, Manistee; *Fourth Vice-President*, Dr. H. A. Hafford, Albion; *Secretary-Treasurer*, Dr. F. C. Warnshuis, Grand Rapids.

THE ASSOCIATION OF INDUSTRIAL PHYSICIANS AND SURGEONS, at its second annual meeting held in Bay City, Mich., May 25, 1921, elected the following officers for the ensuing year: *President*, Frank C. Warnshuis, Grand Rapids; *Vice-President*, Dr. Guy L. Kiefer, Detroit; *Secretary and Treasurer*, Dr. G. C. Pemberthy, Detroit.

THE EAST TENNESSEE MEDICAL ASSOCIATION, at its regular meeting held in Maryville, May 20, 1921, elected the following officers for the ensuing year: *President*, Dr. E. C. Anderson, Chattanooga; *Vice-President for Upper East Tennessee*, Dr. J. W. Wallace of Johnson City; *Vice-President for Lower East Tennessee*, Dr. E. E. Kimbrough, Madisonville; *Secretary-Treasurer*, Dr. G. Victor Williams, Chattanooga.

THE WISCONSIN ECLECTIC MEDICAL ASSOCIATION at its annual meeting held in Milwaukee, June 3, 1921, elected the following officers for the ensuing year: *President*, Dr. R. S. Rodeker, Holcombe; *First Vice-President*, Dr. J. H. Alexander, Belmont; *Second Vice-President*, Dr. F. J. Thompson, Madison; *Corresponding Secretary*, Dr. F. C. Haney, Watertown; *Treasurer*, Dr. A. A. Duclos, Milbourn.

THE PENNSYLVANIA ECLECTIC MEDICAL ASSOCIATION, at its annual meeting held in Harrisburg, June 1, 1921, elected the following officers for the ensuing year: *President*, Dr. F. J. Livingston, Johnstown; *First Vice-President*, Dr. W. J. Rouse, Ambler; *Second Vice-President*, Dr. H. E. Heacock, Bethlehem; *Secretary*, Dr. M. V. Hazen, Harrisburg; *Treasurer*, Dr. N. M. Glann, State College.

THE WEST VIRGINIA MEDICAL ASSOCIATION at its annual meeting held in Charleston May 25, 1921, elected the following officers for the ensuing year: *President*, Dr. George A. McQueen, Charleston; *Secretary*, Dr. Robert A. Ashworth, Moundsville; *Treasurer*, Dr. Hugh G. Nicholson, Charleston.

THE MISSOURI STATE MEDICAL ASSOCIATION, at its annual meeting held in St. Joseph, May 26, 1921, elected the following officers for the ensuing year: *President*, Dr. A. H. Hamel, St. Louis; *First Vice-President*, Dr. B. W. Hays, Jackson; *Second Vice-President*, Dr. A. C. W. Russell, Springfield; *Third Vice-President*, Dr. Thornton E. Moore, Trenton; *Fourth Vice-President*, Dr. C. O. Cuppaidge, Moberly; *Fifth Vice-President*, Dr. Horace W. Carle, St. Joseph; *Secretary and Treasurer*, Dr. J. E. Goodwin, St. Louis.

THE MISSOURI STATE ROENTGEN SOCIETY, at its annual meeting held in St. Joseph, May 26, 1921, elected the following officers for the ensuing year: *President*, Dr. H. J. Ravold, St. Joseph; *Vice-President*, Dr. O. W. Swope, Kansas City; *Secretary and Treasurer*, Dr. Edwin C. Ernst, St. Louis.

THE OHIO STATE ECLECTIC MEDICAL ASSOCIATION, at its annual meeting held in Columbus May 19, 1921, elected the following officers for the ensuing year: *President*, Dr. B. H. Nellans, Cincinnati; *Vice-Presidents*, Dr. W. H. Carey, Belfontaine, and Dr. W. L. Werner, Akron; *Secretary*, Dr. S. J. Wuist, Dayton; *Treasurer*, Dr. J. S. Futter, Lima.

THE PERRY COUNTY (PENN.) MEDICAL SOCIETY, at its monthly meeting held in Blain, May 31, 1921, elected the following officers for the ensuing year: *President*, Dr. Harvey W. Woods, Balin; *Secretary*, Dr. M. I. Stine, New Bloomfield; *Treasurer*, Dr. C. E. Delancey, New Port.

THE MEDICAL WOMEN'S CLUB OF CHICAGO, at its annual election held at the Chicago College Club, June 1, 1921, elected the following officers for the ensuing year: *President*, Dr. Katherine Richt; *First Vice-President*, Dr. Nora Roger; *Second Vice-President*, Dr. Mary E. Hanks; *Secretary*, Dr. Blanche Burgner; *Treasurer*, Dr. Margaret Riley.

Obituary Notes.—Dr. WILLIAM T. JENKINS of this city, died after a long illness on June 25. He was born in Holly Springs, Miss., in 1855 and was graduated from the medical school of the Univer-

sity of Virginia in 1879. In 1887 he began practice in this city. He was health officer of the Port of New York in 1892 when the country was threatened with a cholera epidemic and by stern measure of quarantine prevented its introduction into this city. After his term as health officer of the port expired he was appointed in 1898 health commissioner of New York City, and later was made a member of the State Health Department.

Dr. YANCEY BLALOCK of Walla Walla, Wash., a graduate of Jefferson Medical College, Philadelphia, in 1884, died of pneumonia on May 12, at the age of sixty-one years.

Dr. FREDERICK MARSHALL DAVENPORT of Scranton, Pa., died in a local hospital on May 15, at the age of fifty years. He was graduated from Jefferson Medical College in 1905.

Dr. SAMUEL ANDREW JOHNSTON of Indianapolis died from cerebral hemorrhage on May 20, at the age of forty-four years. He was graduated from the Medical College of Indiana, Indianapolis, in 1902. He was a member of the American Medical Association and an associate in rhinology, laryngology, and otology in the Indiana University, Bloomington.

Dr. MARTIN J. NEVINGER, a graduate of Hahnemann Medical College, Philadelphia, in 1898, and a member of the staff of the Women's Hospital, Philadelphia, died, on May 26, following an operation, at the age of forty-four years.

Dr. RIVES ANDREW MANKER of Memphis, Tenn., a graduate of Memphis (Tenn.) Hospital Medical College in 1908, died from heart disease, on May 19, at the age of thirty-eight years.

Dr. FRANCIS NELSON PILCHER of Columbus, Ohio, a graduate of the Columbus (Ohio) Medical College in 1891, died on May 18, at the age of fifty-three years.

Dr. JAMES P. DICE of Xenia, Ohio, died from pnuemonia on May 18, at the age of seventy-nine years. He was graduated from the Eclectic Medical Institute, Cincinnati, in 1869.

Dr. GIDEON V. BACHELLE of Chicago, a graduate of Rush Medical College in 1867, died on May 23, at the age of seventy-five years. He was a veteran of the Civil War.

Dr. SOLOMON HENRY DESSAU, formerly of New York City, died of arteriosclerosis at his home in New Rochelle, N. Y., on June 11, at the age of seventy-three years. He was a graduate of Jefferson Medical College in 1868, and formerly pediatrist at the New York School of Clinical Medicine. He was a member of the New York Academy of Medicine and at one time vice-president of the Medical Society of the County of New York.

Dr. CLINTON STUART KERR of Emlenton, Pa., a graduate of the Cincinnati College of Medicine and Surgery in 1876, died on May 20, at the age of seventy-two years.

Dr. JESSE P. REX of Richmond, Va., a graduate of the Medical College of Virginia, Richmond, in 1903, died on May 21, at the age of forty-two years.

Dr. FRED C. VOGEL of Cincinnati, Ohio, a graduate of the Ohio Medical College, Cincinnati, in 1900, died on May 18, at the age of forty-five years.

Dr. WILLIAM K. LOUGHRIDGE of Omaha, Neb., a graduate of the Lincoln Medical College in 1894, died on May 19, at the age of forty-eight years.

Correspondence.

REMOVING STAINS OF PICRIC ACID.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: One drawback to the use of picric acid in the preparation of the skin previous to operation is the long lasting yellow stain. We find that turpentine removes it very rapidly, whether applied shortly after the operation or much later.

G. K. DICKINSON, M. D.

280 MONTGOMERY STREET,
JERSEY CITY.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 3, 1921.

Coal Fires and Impure Air.—London has long been notorious for its excessively dirty fogs, due as is well known to the immense consumption of soft coal, both in private houses and in factories. It is also a matter of common knowledge that this grimy atmosphere is unhealthy and the direct and indirect cause of a good deal of disease. Although this state of affairs can be remedied, nothing really practical has been done in this direction up to the present time. The recent improvement of the atmospheric conditions in London, Manchester, Glasgow, and other industrial cities in which much soft coal is burned, rightly attributed to the shortage of coal fires, is an outward and visible sign to the public of the way in which under normal conditions the air is polluted by smoke. In 1914 Sir Herbert Samuel, then president of the Local Government Board, appointed a committee to inquire into the question. The work was necessarily suspended during the war, but last year the committee was reconstituted with Lord Newton as chairman. Investigations have been made, both in London and the chief commercial centers, but at the moment they are more or less in a state of suspense owing to the existing industrial situation. In an interim report published recently, however, the committee recommend various smokeless methods available for supplying heat to dwelling houses; it may be mentioned that at least half the smoke in London is due to domestic fires. Moreover, the Ministry of Health issued a short time ago a special memorandum drawing the attention of the local authorities to the recommendation. It is understood that Sir Alfred Mond, the new Minister of Health, attaches great importance to the work of the committee from the health point of view.

Proposed National Conference for the Suppression of Vermin.—Although a law has been passed making it a penal offence not to destroy rats and other vermin, so far efforts to exterminate these disease-carrying destructive pests have been unsuccessful. This is largely due to apathy and a lack of coordinated methods. An extraordinary lethargy is manifested on all sides with regard to the destruction of vermin, although it is well known that the damage done by rats amounts to many millions of pounds a year. That rats are a menace to the human race because they carry certain diseases, a very deadly one in particular, is not well understood by the community. Edu-

cational propaganda is needed on this point. However, it is absolutely true that without coordinated efforts it is hopeless to imagine that rats can be exterminated or that their numbers can be even appreciably lessened. There is no more cunning and wily animal than the rat. He seems to be endowed with an intelligence almost human. In order to have any success a campaign against rats must be waged not only with coordinated vigor but well-planned in every detail. The conference called for should have the result of awakening public concern in the rat peril and from its discussions should be evolved a campaign war on these vermin conducted strategically and with due regard to the rat's intelligence. The matter is a serious one and should be considered seriously.

Treatment of Manifest Concomitant Strabismus.—At the recent Annual Congress of the Ophthalmological Society of the United Kingdom a discussion was held on the treatment of manifest concomitant strabismus which was opened by Mr. Claud Worth. Perhaps the most valuable contribution to the discussion was by Mr. A. J. Ballantyne, who thought that the first step in the treatment of concomitant convergent squint should be an estimation of the refraction, and the prescription of suitable glasses to be worn constantly. In many cases the wearing of these with training, if necessary, sufficed. His patients were all quite young children. The largest degree of squint corrected with 40° in a patient 18 months old, whose squint had lasted two weeks. In most of his cases the angle was 15° or less. In some the eye was already amblyopic. In the majority of cases he was of the opinion that the amblyopia was the result of the squint, hence there was all the more encouragement to attempt to restore vision in the squinty eye. He applied atropine more or less continuously to the sound eye. He was now inclined to operate at an earlier age than formerly. Advancement alone in many cases would bring about an approximately straight position of the eyes; he had never seen over-correction caused by advancement or muscle folding, therefore he would not hesitate to operate at any age. He preferred muscle folding in the youngest children. He rarely did tenotomy of the internal rectus, and never as the sole means of correcting the squint. In children it was wise to do too little, rather than too much; and if tenotomy was performed, it should be as a last resort. Cases in young children often suggested the existence of a state of excitability and instability of the accommodation and convergence centers, and in these cases the operative treatment of the strabismus was apt to be very disappointing. Failure in these cases was not due to slipping of the stitches, but to looking for a remedy of a mechanical kind for what was really a functional error. His results from training of fusion had been disappointing. We were apparently born with a certain racially-acquired degree of binocular equilibrium, but the finer coordination of the eyes necessary for binocular vision required to be learned, like the act of walking, by each individual, and the most useful line of inquiry would be along the evolution of binocular vision in the young child. Mr. E. E. Maddox referred to the numerous cases of squint in which the child was unable to fix its attention. Attention had a great effect, especially on the fusion faculty, and the defect in many children was not the absence of the fusion faculty, but the lack of stimulus to action. To correct hypermetropia some occupation on near objects should be provided. Squinting children should be kept from reading early, and their parents should let them use large objects. Moreover, they should be encouraged to look upward, as that produced a less tendency to divergence. He considered that the amblyoscope was very valuable in diagnosis.

State Aid for Hospitals.—It is understood that the long expected report of Lord Cave's Committeen on Hospitals will be published in about a week's time. It is expected that the recommendations will not interfere with the voluntary principle of management and that grants of money from the public exchequer will be made to them. It is suggested, it is said, that the country shall be divided into hospital areas, and that arrangements shall be made for a closer coordination of the work under associations. While it is not recommended that the Government, in virtue of grants, should interfere in control and management, it is probable that periodical inspection and representation on boards of management will be required. Some arrangements for the financial support by approved societies and business firms are expected to accrue also as a result of these recommendations. In my next letter, if by the time it is written the report of Lord Cave's committee has been published, I will deal with the question at length.

The North European Congress on Venereal Disease.—The British Red Cross Society nominated the following three delegates to the North European Conference on Venereal Diseases, which met recently in Copenhagen, Colonel L. W. Harrison, Dr. F. N. Kay Menzies, and Mrs. C. Neville Rolfe, organizing secretary of the National Council for Combating Venereal Disease. The Society for the Prevention of Venereal Disease was ignored completely. Mr. H. Wansey Bayly, the honorable secretary of the Society, was informed by the British Red Cross, in whose hands the appointment of delegates was placed, when he communicated with this body requesting that his society might be represented at the conference, that it was impossible because delegates, members of the National Council, had been elected already. The *Medical Press and Circular*, May 25 last, referring to the question editorially, expressed surprise that the League of Red Cross Societies in Geneva should have decided to adopt the National Council for Combating Venereal Disease as the recognized channel in Great Britain for communication on these subjects. It is regarded in this editorial as an impolitic position to have taken up, and not least on account of the strong opposition which exists against the policy pursued by that body. It is contended that the Society for the Prevention of Venereal Disease have established their case for self-disinfection, which the National Council cannot dispute, and yet, despite this, the society is refused a hearing, and the Red Cross

Conference will make it appear that the National Council represents an uncontested opinion upon this subject in England.

London's Water Supply.—Giving evidence before the Committee of the House of Commons, which is considering the Metropolitan Water Board Bill, by which the Board seeks power to raise some £10,000,000 to extend the Littleton reservoir, and lay down additional mains, Mr. H. E. Stilgoe, chief engineer to the Board, stated that baths accounted for a very considerable proportion of the water used. Twenty gallons were sufficient for a bath, but most people were not satisfied with that. In many of the best houses in London up to a few years ago there was not even a bath room; but now every house that was put up had a bath; in fact, the bath habit was growing to such an extent that the prevention of waste would not give the water necessary to meet the increased demand. Unless this scheme were carried through the health of the community would be menaced.

LETTER FROM BELGIUM.

(From Our Own Correspondent.)

LIÈGE, June 10, 1921.

The University Foundation, established through the generosity of the "American Commission for Relief in Belgium," has just completed its first undertaking. It has already proved its utility by numerous benefactions, particularly appreciated at this time when the intellectual classes, both scientists and students, are struggling with many difficulties caused by the high cost of living. It has granted more than three hundred study loans to students in our universities and high schools; it has sent twenty-four bursar students to the United States; it has granted subsidies for the publication of journals and books; it has decided to defray the cost of publication of a number of scientific works, thereby rendering an immense service to those who have been prevented from publishing valuable works by the high cost of printing, and it is also establishing bursaries to enable certain of our students to take courses in some of the European universities.

A New Medical School in Brussels.—The Rockefeller Foundation announces officially that it will contribute 43 million francs in a total of 100 million needed for the establishment of a school of medicine in the Free University of Brussels.

Scientific Reciprocity.—The ministers, in whose hands it lies, of France and Belgium are about to sign an agreement, long urged by scientific men of both countries, providing for mutual recognition of diplomas and exchange of professors in the higher and the technical schools. A permanent Franco-Belgian academic commission will also be established.

Practical Guide to Tropical Hygiene.—This is the title of a work recently written by Dr. O. Devalkeneer and published by the Union Coloniale Belge of Brussels. In all colonization, the author declares, the health of the colonists and the betterment of the natives are the most important factors which must never be neglected. After the indispensable anatomical and physiological introduction he treats of his subject in five sections. In the first he considers the qualification necessary to fit us for the life of a "colonial"; in the second he sets forth the difficulties to be surmounted; hygiene in relation to the individual diseases encountered in the tropics is studied in the third part; the fourth is a treatise in tropical first aid, and in the fifth the author discusses the social reforms in their relation to health in the tropics. An appendix is devoted to the venereal diseases. In brief, this is a work to be used by all contemplating a journey to Africa and to be studied carefully by those who have decided to take up their life on that continent.

The "Anvers Médical."—This local medical journal of the city of Antwerp is about to make its reappearance, notwithstanding the difficulties in the way of such an undertaking at the present time. The editorial staff is composed of Drs. P. François, Hensotay, Dokx, Watry, Brandès, Fonteyne, Dineur, J. François, and Delbeke.

3. The Essential Factors of Cancer Causation. James W. Shannon.
4. Two Cases of Acaraphobia. Abraham Myerson.
5. Recent Progress in Proctology. T. Chittenden Hill.

3. Visceroptosis as a Cause of "Stomach Trouble."—T. Chittenden Hill reports four cases of visceroptosis presenting "stomach symptoms." A lack of good physical development and subnutrition are commonly associated with the condition. The diagnosis is based on evidence obtained in the history, physical and roentgen examinations. Organic disease should be excluded in these and by suitable laboratory tests. Treatment should be directed toward the patient's mental condition, toward the subnutrition, and toward the mechanical handicaps.

4. Two Cases of Acaraphobia.—Abraham Myerson cites two cases of acaraphobia, dermatophobia, or parasitophobia, a mental state recognized by dermatologists and loosely defined by them as an obsession, neurosis, or mania, which occurs with pruritis, and which, concisely, is the fear of insects or bugs. These two cases indicate that there is an important group of diseases theoretically which have not been studied by psychiatrists. It is desirable that the acaraphobia of the dermatologist receive the attention of psychiatry, for here are mental symptoms definitely referable to physical conditions in a manner that is at once unique and important.

6. Visual Errors in General Practice.—Louis H.

Schwartz cites seven cases in point, from which he holds it to be evident that, although no one would attempt to attribute the various symptoms mentioned as due to imperfect vision alone, nevertheless a great advantage is obtained by learning whether or not the eyes are emmetropic (with or without lenses). And, inasmuch as the question of normal vision can be determined, it is worth while doing in every case where there may be any suspicion or even possibility of the eyes being at fault. One might imagine that if a patient had any defect of sight he would be pretty sure to know about it. Yet the experience of every ophthalmologist is that some persons may be totally blind in one eye without even suspecting it. Not only do most physicians fail to test the vision, but patients sometimes actually complain of ocular disturbance and the doctors pay no attention to the fact, possibly just because these practitioners do not do eye work. Every man doing general work should have a Snellen test card in his office and should ascertain the visual acuity. Each eye must be tried separately.

3. Cinchophen, Neocinchophen, and Novaspirin in Rheumatic Fever. Comparative Therapeutic Efficiency, Toxicity, and Renal Functional Effects.—Hanzlik and Scott and their collaborators formulate the following conclusions from their observations: 1. Cinchophen gave partial relief from symptoms in rheumatic fever with doses of from 3 to 6 gm., and complete relief with doses of from 10 to 13 gm. (seven patients), while neocinchophen required a somewhat higher range of dosage, namely, from 3 to 8 gm. for partial, and from 11 to 16 gm. for complete relief (three patients). 2. Novaspirin was therapeutically worthless in the treatment of rheumatic fever (three patients) not giving even partial relief from subjective symptoms. This is due to inadequate concentration of salicyl in the tissues, as indicated by the low (from 14.8 to 23.4 per cent.) excretion of salicyl in urine after large doses of the drug. 3. Large doses of cinchophen and neocinchophen, such as are necessary in the treatment of rheumatic fever, produce characteristic symptoms of salicylism ("toxicity") which, however, are less pronounced than those caused by corresponding doses of salicylate. Cinchophen differs from salicylate by causing epigastric pain owing, presumably, to local irritation by the drug. Pain in the epigastrium was absent after large doses of neocinchopen, presumably because of its relatively low solubility in water and weak alkalis, possibly also because it is an ester. 4. Large doses of cinchophen were found to slow the pulse rate of both febrile and afebrile individuals, and the same occurred after neocinchophen in febrile patients. Therefore, the cardiac slowing produced by cinchophen is due to a direct depressant action on the circulation. 5. Cinchophen is injurious to the kidney, as indicated by the occurrence of albuminuria, and sometimes casts and white blood corpuscles, in the majority of seven individuals that were observed, and a diminution in the excretion of phenolsulphonephthalein in the five individuals that were studied. Neocinchophen is variable, albuminuria and a diminution in the excretion of phenolsulphonephthalein occurring in about one-half of the nine individuals that were observed. 6. As compared with salicylate, cinchophen appears to be about equally efficient, while neocinchophen is somewhat less efficient, as judged by the dosage necessary for therapeutic relief in rheumatic fever. The symptoms of "toxicity" are about the same and renal injury somewhat less after cinchophen, and both the "toxicity" and the renal injury are less pronounced after neocinchophen than after salicylate in corresponding doses. 7. Further observations on the therapeutic use of cinchophen and neocinchophen in rheumatic fever, and a study of their pharmacologic actions, are desirable.

7. Influence of Menstruation on the Food Tolerance in Diabetes Mellitus.—Jacob Rosenbloom reports the study of two cases of diabetes mellitus in which the patients lost all their food tolerance with the onset of their menstrual period. It is well known that before or during menstruation there is present an increased function of the chromaffin tissue as shown by the facts that: 1. In the premenstrual period the glycosuric action of epinephrin is increased. 2. There occurs a swelling of the thyroid gland in the premenstrual period. 3. The suprarenal cortex increases in size. 4. The interstitial glands increase in size. 5. The pituitary gland increases in size. On account of these fats the writer believes that the explanation of the loss of food tolerance in the two cases described is due to some temporary alteration in the function of the gonads, either an increased secretion or a lack of correlation with other of the endocrine organs.

1. An Address on Asthma.—Arthur F. Hurst, after discussing the etiological factors concerned in asthma, considers the treatment under three heads: (1) The irritable bronchial center; (2) the chemical, reflex, and psychical stimuli which may affect the center; and (3) the attack itself. He has found that the irritability of the bronchial center can be to some extent reduced by giving between 3 and 5 grains of caffeine, with double the dose of phenazone, when the patient feels slightly asthmatic and fears that an attack will develop later, as, for instance, immediately after lunch and dinner or on going to bed. When asthmatic attacks are caused by food proteins all that is generally necessary is to exclude from the diet the food to which the patient is found to be most sensitive by the cutaneous test. A patient can often free himself from asthma by simply avoiding any animal to which he has been found to be sensitive. If avoidance of the animals, or other causative factor, is impossible, or does not relieve the asthma, desensitization should be undertaken with the specific proteins. Idiopathy to bacterial toxins can generally be overcome by vaccination in the ordinary way with organisms isolated from the patient's bronchial secretion or material obtained from other infective foci. The daily life of each patient should be investigated in minute detail in an attempt to find some special toxic idiopathy other than the familiar ones described, which may be in part responsible for the asthma. Asthma caused by a gastrobronchial reflex can be avoided by eating hardly anything for dinner, which should be as early as possible, and nothing at all on going to bed, as the reflex only comes into play as the day advances and the patient becomes more tired. The intestinal-bronchial reflex comes almost entirely from the pelvic colon and rectum, and regular habits and exercises to overcome dyschezia are generally sufficient to keep it in check. Aperients should be avoided as far as possible, but in some cases a small weekly dose of infusion of

senna is needed to prevent a fecal accumulation from forming. Psychotherapy is useful only in so far as explanation of the mechanism involved may lead an asthmatic to take a less hopeless view as to his chance of complete recovery. An attack of asthma can most readily be cut short by the subcutaneous injection of adrenalin. In many cases a single minim of 1 in 1000 adrenalin chloride is enough, more than two minims being rarely required. For slight attacks and for the feeling of dyspnea, which may persist throughout the day when severe attacks occur at night, atropine and cocaine may be used with an atomizer.

5. Observations on the Urea Concentration Tests in the Psychoses.—J. Walker gives as the primary object of this investigation the discovery of whether there is any undue prevalence of renal inefficiency in the psychoses, as determined by the urea concentration tests in the blood and urine, and, if so, with what forms of mental disorder this condition is associated. It was found that the urea concentration in the blood in the cases examined is subject to wide variations, and therefore is an unreliable guide as to the state of health of the kidneys. The urea concentration in the urine gives more reliable information. A low concentration should be regarded only as a confirmation of other evidence. Anomalous results, as regards urea concentration in both blood and urine, apart from kidney disease, are as demonstrable by available methods common in the psychoses. In dementia precox a low concentration of urea in the urine is found to coexist with polyuria and a state of acidosis.

3. Dual Radiotherapy in Malignant Disease.—S. Gilbert Scott, for some years has based his therapy on the following principles: (1) Full cell absorption; (2) production of a large number of heterogeneous rays; (3) a filter only thick enough to protect the skin and to cut out rays of little or no therapeutic value. The shortcomings of the present methods are: 1. The dose administered to the deep-seated and scattered pathological cells is too small. 2. The area treated is much too limited. The dual method advocated by the writer consists of two separate installations of which one operates a tube in front, the other a tube at the back of the patient, who is in the sitting position, both tubes running simultaneously. After the first full dose has been administered the direction is changed, so that the radiation is now from side to side, the arms being forward and raised. In this way the deepest parts of the body are subjected to radiations from the four points of the compass, and the resulting cell absorption must be very much greater than with the present methods, although the more superficial or skin dose, controlling superficial recurrences, remains the same. By this method, which may be described as a combined crossfire, the deficiencies of current methods noted are avoided. In other words, by working both tubes at the same time from both sides of the body a larger dose is administered to the deeper pathological cells, and a very large area is covered. It cannot be definitely stated how frequent the treatment should be; this must depend, to a certain extent, on the blood changes and other symptoms, the significance of which is still debatable. The writer now administers treatment weekly; anteriorly and posteriorly the first week, the second week from both sides, the total dose being 40 X through 3 mm. of aluminum in each week. Although many tolerate it, there are some who cannot stand even this dose. The secondary phenomena so far noted are of interest. Few can tolerate the full 80 X dose, nausea and vomiting, lasting from several hours to three days, appearing shortly after treatment. If, however, the dose is halved—two opposite areas only being treated instead of four—the patients may experience a feeling of well-being.

Treatment of Melancholia with Heroic Doses of Strychnine.—Hartenberg, well known for his advocacy of large doses of strychnine for neurasthenia, has obtained five successes from the same resource in melancholia. He had frankly the object of saturating the organism in the aim of producing a cure. Opium he insists is only a palliative and symptomatic remedy. To obtain any action from the drug 5 centigrams must be taken within twenty-four hours. This, however, is only the minimum dose, and to cure the disease the subject must be placed in the condition of subacute strychnine poisoning. The patient is profoundly impressed, his nutrition is stimulated, and he resumes his former interest in life. It may be necessary to give along with the alkaloid one of the following sedatives: codeine, chloral, bromides, veronal, and valerian, alone or in combination. The indication for these sedatives comes from the disease and not from overaction of the strychnine. The latter is given by the mouth as a rule and by hypodermic only in cases in which buccal administration is refused. A solution is made of 1/100 and of this seven drops are given three times daily or twenty-one drops in twenty-four hours, which equals 1 centigram of the drug. On each subsequent day one drop of solution is added to each dose, making twenty-four, twenty-seven, thirty, etc., drops daily until the subject is getting his 5 daily centigrams. By this time about a month has elapsed in which no improvement has occurred or is expected. The dose is then pushed further without rule until the physiological action is obtained and the patient has improved. At this juncture one slowly diminishes the dose by three drops daily until the original dose has been reached.

Le Progrès Médical.

March 26, 1921, xlix. 13.

Isolated Vitamines in Therapeutics.—Peuret considers this subject, starting with certain postulates as follows: the rôle of vitamines in nutrition is one of potential: chemically the vitamines range themselves with the hydrolytic derivatives of nucleinic acid; in physiology the vitamines are regulators of growth and operate through other functions—those not only of internal but external (digestive) secretions: vitamines are not stored any more than they are manufactured in the body; there is but one vitamine, however much there may seem to be three, four, or more; there are not only avitaminoses, but pathological states deserving the name of dysvitaminoses. Our recent knowledge of vitamines owes much to the Italians, Lorenzini, Ganassini, and Mancini, who have isolated and worked with a definite vitamine. Vitamine-bearing foods give results in marked deficiency diseases, but have no independent therapeutic activity—for one reason because they must be given by the mouth. Isolated vitamine is given by hypodermic. In his own practice the author cites Barlow's disease as a type of avitaminasis which is readily relieved by giving fresh milk and orange juice. That is in most cases we obtain prompt enough results, although recovery may be tedious and even remain in abeyance. The Italians quoted above appear to believe that the benefit from orange juice is not entirely attributable to the vitamine content, which is not striking, but to the organic acid present. In rebellious cases in which orange juice seems inert injections of isolated vitamine give relief. The author in a case of unusual degree of anemia from Barlow's disease, which was not benefited by two months' feeding of antiscorbutics, made a prompt recovery under hypodermics of isolated vitamine. The latter should be tested in rickets and in all conditions in which the infant does not thrive.

Gazette des Hôpitaux.

March 17, 1921, xciv. 22.

Death from Ethyl Chloride Anesthesia.—Courtois-Suffit and Bourgeois relate this case in great detail in

connection with fixation of responsibility for the fatal outcome. The patient was a woman and the anesthetic was administered by a surgeon-dentist for the extraction of a tooth. Local anesthesia had been deemed unwise on account of the state of the gums. Before giving a general anesthetic the dentist had the patient examined by a physician and the latter could find no contraindication. At 6 P. M. the ethyl chloride was administered successfully by the same practitioner who had made the examination and the mask was removed to insert a gag. The tooth, which was the first lower molar, was crushed under the forceps. A minute later, the patient having shown signs of returning consciousness, a third ampoule of the chloride (kelene) was given after replacing the mask. It was then noted that the respiration was irregular. Patient was placed on the floor, oxygen administered, tongue tractions and artificial respiration practised, and ether and caffeine injected. A surgeon had also been summoned in haste. Nothing resulted after an hour's work. The husband would make no charge against the medical men, so that the State acted in the usual manner in such cases. A medical examination was ordered by the police commissioner and was performed within forty-eight hours after death. The body was that of a woman twenty-five to thirty years of age, of excellent physique, and practically free from traumatisms and disease with the exception of the bad state of the gums and mouth in general which had been the motive for general narcosis. The condition seems to have been a Vincent's stomatitis. The first molar was broken as a result of the attempted extraction. The lungs and also the trachea were congested. There could be no two opinions about the fatality, which was of the same type as death under other general anesthetics. Nothing antecedent was found which could have contraindicated general anesthesia nor was there any fault of technique. No accusation could have stood against the medical man or dentist. Nevertheless the patient died and something more must be said of responsibility. The latter has been summed up for similar cases and quite recently by Rosenberg. In passing it should be said that the choice of anesthetic could not have been criticised, for ethyl chloride is notably safe. Was too much given? The evidence is against the presumption, for the drug escapes from the body with great rapidity. Was it given with too much force or haste? Successful anesthesia demands that air be shut off for the nonce, according to Tuffier, while others would have the vapor inhaled only when admixed with air. Houzel has recently pointed out that ethyl chloride must never be administered on the suffocative plan, because after the pulmonary tree is completely filled the presence of the gas in the blood may act unfavorably on the myocardium. He even predicted that it would sooner or later cause death by cardiac syncope. His apparatus is devised to secure a gradual administration of the drug. But forced anesthesia, as stated, has its advocates. Study of individual cases has shown that there may be an element of danger in the resumption of ethyl chloride anesthesia after it has once been intermitted. Tuffier saw a death occur in a wounded soldier in this manner, and Malherbe has recently reported another. This may be much more than coincidence that three ethyl chloride deaths give the same history of a return to the anesthetic after interruption. But it may be necessary to interrupt the anesthesia so that the duty of the anesthetist is not obvious in such cases.

Schweizerische medizinische Wochenschrift.

March 31, 1921, li, 13.

Sporadic Hemophilia.—Montanus describes the following case in great detail. The single woman of 28 was attacked on a given occasion with incoercible nose bleed, which finally led to her admission to a hospital. There was no family history of bleeding, which, with the alleged great infrequency of hemophilia in the female, led to a provisional diagnosis of nonhemophilic hemorrhage. But recently the old controversy, thought finally settled, has been revived by the publication of alleged typical hemophilic bleeding in women. The case reported is therefore timely. The usual history and clinical manifestations of the bleeder were absent. There had been slight menorrhagia of late, but nothing unusual. Within a comparatively short interval some of the manifestations of bleeders had been in evidence. Thus after extraction of a couple of teeth hemorrhage persisted for two days, and soon afterward the persistent nose bleed followed without apparent exciting cause. In other words, an acquired hemorrhagic diathesis of unknown origin was present. Blood drawn from the cubital vein failed to coagulate. Most of the remaining history consists of attempts to fix the coagulation time, using normal girls as controls, and of the other usual blood tests all frequently repeated. The nose bleed had ceased on admission to the hospital. There was a residual anemia treated by arsenic and autotransfusion. There were no further hemorrhages and during the hospital sojourn the greatly delayed coagulation time became normal, as likewise the blood counts. In conclusion, here was an ordinary subject who for about three and one-half months was hemophilic. It was shown over and over that something was wrong with the blood coagulability, but outside of this interval the coagulability was normal and even more rapid than normal. The case must be regarded as a transition one between a normal subject and a congenital bleeder.

Wiener klinische Wochenschrift.

March 24, 1921, xxxiv, 12.

Variola Neonatorum.—Morawetz discusses this subject with special reference to the alleged immunity of the newborn. The sort of immunity which may be attributed to maternal variola is left out of consideration. The supposed immunity of the same infants to vaccination should be considered at the same time. Statistics which concern somewhat older children have no bearing on the newborn. In the latter, finds conflict. Wolf who vaccinated 46 infants up to the sixth day postpartum found no immunity such as has been described by others and it is evident that no absolute immunity can exist, although some authors have found as high as 36.5 per cent. for whatever reason. The question of immunity of the newborn to variola in cases where maternal transmission *in utero* can be excluded is best studied in foundling asylums and midwifery institutions. Thus on one occasion an infant was admitted with variola into a ward which contained 14 newborn children. The infant was of course sound on admission, unvaccinated and coming from a smallpox neighborhood. The 15 infants were cared for by one attendant. When the newcomer, who was 3½ months old, developed smallpox, conditions of exposure warranted the expectation that some at least of the newborn would contract the disease. Naturally no time was lost in vaccination, but some infants proved refractory. Of the 14 newborn 8 promptly developed smallpox. While called newborn the actual age at the outbreak of the disease was 2 to 5 weeks. From this we may deduct six days which intervened after the admission of the child before it developed the disease, plus the period of incubation (10 to 12 days). Vaccination was perhaps performed too late to be reckoned as a component of the immunity, though doubtless it mitigated the course of the disease. The five youngest infants had variola in a very mild form while six others did not develop it at all and in the remaining three the course was not severe.

Eserine in Persistent Tachycardia.—Lian and Velti have tested eserine sulphate, 1 to 3 mgms. as a daily dose in eleven cases of permanent tachycardia. The syndrome of sympathicotonus seems amenable to this treatment and some patients felt more or less relief subjectively, although in other cases the improvement was only noted by objective examination. If bromides and valerian give no relief, this substance may be employed. Some of the patients slept better after having taken the eserine. The latter should be carefully supervised, for the patient, if left to himself, will be apt to take too much of the drug. But one mgm. should be given at first and when necessary two, followed possibly in time by a third when the medicine is well tolerated. —*Le Bulletin Médical.*

Book Reviews.

SURGICAL THERAPEUTICS AND OPERATIVE TECHNIQUE. By E. DOYEN. English Edition Prepared by the Author in Collaboration with H. SPENCER-BROWNE, M. B. Cantab. Éleve de l'Institut Pasteur; Physician et Chef de Clinique de l'Institut Doyen. Three Volumes. Royal Octavo. Vol. I, 746 pages, with 1034 illustrations; Vol. II, 680 pages, with 982 illustrations; Vol. III, 811 pages, with 959 illustrations. New York: William Wood & Company, 1920.

DOYEN'S reputation as a diagnostician and operator was world-wide; hence we may safely say that this work was written by a master in both the diagnosis and treatment of surgical conditions. Furthermore, it was written on the basis of his own experience and his own, often original, technique, and is far from being a simple compilation of the work of other authors. This does not mean that he had his own original method for doing everything but that the technique for any individual operation, whether exactly as devised by some other surgeon or as modified or independently conceived by him, is given as he operated when the manuscript was written, thus giving what he considered the best method of handling the situation and without presenting a multitude of methods from which the reader must choose.

In Doyen's Introduction in Vol. I he gives a brief historical review of the evolution of surgical practice, then proceeds with the discussion of methods of operating and calls attention to the value of rapid and at the same time careful work. Doyen contributed much to the surgeon's armamentarium, for he was a mechanical genius and at least 40 pages are required for the description and illustration of instruments and other apparatus devised or radically modified by him. Following this introductory chapter the volume is divided into two parts.

The first part, comprising about 475 pages, is devoted to matters pertaining to general surgical technique, the pre- and postoperative care of the patient surgery of the blood vessels and nerves, autoplastic surgery, electrocoagulation treatment of malignant growths, and many other subjects. In Part II the usual operations on the head, including certain special operations on the eye and ear, are described and illustrated. The text relating to intracranial surgery is disappointing, particularly as regards indications for operation, and some of Doyen's methods seem somewhat antiquated as compared with current American practice; but on the whole this volume is very satisfying.

In Vol. II the consideration of operative conditions of the head, face, and neck is continued, then those of the thorax, upper and lower limbs. Doyen's method of covering the various conditions and outlining operative treatment is particularly terse. He usually gives a brief description of the pathology or clinical characteristics, indications or contraindications for operations, surgical anatomy when worth while, a plate showing the instruments needed, then directions for operation. For purposes of description, operations are usually divided into a number of stages, each stage from incision to closure being covered in as few words as possible without sacrificing clarity. This brevity in the text is made possible by the almost innumerable and most excellent illustrations which, with their underlying legends, not only supplement the text but sometimes almost make text unnecessary. One of the most interesting chapters is that on the surgery of the lung and pleura, in some phases of which Doyen was among the pioneers. Another important chapter is that on operations on the mediastinum. Operations on the extremities generally follow the usual well known methods; but there are some innovations and an opportunity is also afforded for the demonstration of the use of many special instruments devised or modified by Doyen.

Throughout this volume, as in the first, there are almost constant references to illustrative cases which have been met with in the author's practice, and a remarkable series of illustrations.

From the Translator's Preface to Vol. III we learn that publication of this volume was long delayed through the death of Doyen and the translator's absence on war work. However, Doyen had reviewed all but the last pages of the manuscript, hence practically the entire text may be considered to accord with his ideas. This volume deals with the surgery of the abdominal wall, peritoneum, liver and bile passages, spleen, pancreas, stomach, intestines, and retroperitoneal space, and also the genitourinary organs of both the male and female. Portions of this volume are extremely valuable and interesting; others disappointing.

There is a résumé of Doyen's researches into the physiology of the stomach and gastric digestion, and considerable space is devoted to the serodiagnosis of cancer and the treatment of visceral cancer by a vaccine composed of the dead bodies of the *Micrococcus neoformans*, this latter being very interesting even if not generally accepted as of value. It is in the section devoted to general abdominal surgery that the American surgeon will be particularly disappointed; for not only are some of the incisions recommended unnecessarily mutilating but many of the methods recommended in the treatment of lesions of the gall-bladder, stomach, and intestines have been practically obsolete in this country for many years, while many of the newer and generally employed methods are not even mentioned. It is also apparent that Doyen did not have the advantage of as expert Roentgen diagnosis of diseases of the gastrointestinal tract as we are accustomed to; for he seemed to consider it of comparatively little value in the differentiation of gastric cancer, gastric ulcer, and other upper abdominal conditions and he dismisses it in a few words. There are, however, many portions of the text, in both the section devoted to general abdominal surgery and the special sections devoted to genitourinary surgery and gynecology, which will be instructive to even the most expert surgeon of this or any other country; there are almost innumerable illustrations of marvelous exactitude, including those depicting anatomical relations after frozen sections; each volume bristles with the aggressive personality of the author; and the set will undoubtedly make a very valuable addition to any surgeon's library.

A PRACTICAL MEDICAL DICTIONARY of Words Used in Medicine With Their Derivation and Pronunciation, Including Dental, Veterinary, Chemical, Botanical, Electrical, Life Insurance and Other Special Terms; Anatomical Tables of the Titles in General Use, and These Sanctioned by the Basle Anatomical Convention; Pharmaceutical Preparations, Official in the U. S. and British Pharmacopœias and Contained in the National Formulary; Chemical and Therapeutic Information as to Mineral Springs of America and Europe, and Comprehensive Lists of Synonyms. By THOMAS LATHROP STEDMAN, A.M., M.D., Editor of "Twentieth Century Practice of Medicine," of the "Reference Handbook of the Medical Sciences," and of the "Medical Record." Sixth revised edition. Illustrated. Price, $7.00. New York: William Wood and Company, 1920.

SUFFICIENT time has elapsed since the appearance of the present edition of this now so familiar book to enable even the casual consultant to recognize the fact that the author has given a revision and not a reprint of the previous edition. Indeed, the many terms added, including war-born words and phrases, and their definitions, have necessitated the enlargement of the volume by twenty pages. There is no evidence here of the "vanishing C." for the author consistently adheres to the method adopted in the first edition, and so one finds *caryocinesia*, and a whole family of *caryos*, *catabolism*, and a whole family of *cats*, with many other *c's* of more or less common or uncommon usage. When one has applied the test of frequent reference, covering a wide range of subjects, one marvels that so many words and definitions can be found within the compass of the 1131 pages which comprise the body of this valuable dictionary. And whether one agrees or disagrees with the author in some of the forms to which the preference is given, there is no danger in any case of a negative search for a word or a definition as the result of his usage, since he gives sufficient indication under the expected prefix—for example—to guide one to the expected form.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventy-Second Annual Session, Held in Boston, June 6-10, 1921.

(Special Report to the MEDICAL RECORD.)

(*Concluded from vol. xcix, p. 1119.*)

Studies on Diphtheria.—Dr. JOHN HOWLAND of Baltimore presented this paper in which he said that the course of diphtheria was very deceptive. The patient might recover from the first alarming symptoms after the administration of antitoxin to fall victim to complications at some later time. There might be symptoms of cardiac and circulatory complications in the second and third week after the onset of the disease. There might also be complications involving the nervous system, particularly those characterized by peripheral neuritis, perhaps in the seventh or eighth week, as Dr. Mixsell had shown that post diphtheritic diaphragmatic paralysis occurred about the thirty-fifth to the thirty-seventh day. It had been conclusively demonstrated that the toxin of diphtheria had an extraordinary affinity for tissue cells and became so closely bound to the cells that it could be dislodged with the greatest difficulty, and after a time not at all. If two fatal doses of antitoxin were administered to an animal, it could be saved by different amounts of antitoxin depending upon the time of their administration. If the antitoxin were given within the first minute, 0.1 of a unit would save the animal; at the end of an hour it would take 30,000 units, and at the end of seventy minutes the animal could not be saved at all. Treatment was effective not because it neutralized the antitoxin that had been absorbed but because it neutralized it before it found its way into the circulation. That was why the prognosis of diphtheria depended not so much upon the extent of the membrane as upon the length of time it had existed. Clinically it was a striking and shocking experience to see a child with a severe form of diphtheria rapidly improve after the administration of antitoxin and become afebrile, and then within twenty-four to forty-eight hours suffer a change, show great pallor, aversion to food, a rapid heart rate, abdominal pain and albumin in the urine, followed by death. Many of these children died and if they did not die convalescence was slow and there was considerable loss of weight. He had long been interested in finding an explanation of this process. He had made studies on the urine in these cases many years ago in Willard Parker Hospital. They had long wished to study the output and the total nitrogen excretion in patients in nitrogenous equilibrium. But these patients did not take enough food to sustain a nitrogenous equilibrium. Dogs were therefore used. There was a preliminary period during which the dogs were kept in nitrogenous equilibrium, and measured doses of diphtheria toxin were administered. During the first two days following the administration of the toxin there was fever and an increase in the total nitrogen and creatinine output, but it did not show a significant rise. Following this for two or three days the animals seemed perfectly well. Then on the sixth or seventh day there appeared a second period of reaction. During this period the temperature of the animals increased and the total nitrogen showed negative balance. In the majority the loss of nitrogen was very striking. The same was true of the creatinine though it did not run parallel with the total nitrogen. The excretion of nitrogen was something like 50 per cent. above normal. The weight continued practically the same during the first and second febrile periods and then began to fall very sharply. This sudden excretion of nitrogen could not be regarded as a damming back of nitrogenous products and then a sudden excretion. It could only be explained as being due to a destruction of the body cells. There was also experimental evidence to show that these changes in nitrogenous excretion occurred when the toxin was injected into the myocardium. Experimental evidence also went to show that the nitrogenous excretion was due to the infection and not to the fever.

Dr. DENNETT L. RICHARDSON of Providence stated that clinical observations corresponded with this experimental work. In his experience diphtheria patients frequently died in the second stage. They died either during the acute process, or the membrane might clear up and the fever subside and the child would look quite well, then after the twelfth or fourteenth day there would be pallor, prostration, changes in the pulse, and the child would die in the second week of the disease. It had been his experience that if children with these symptoms lived fourteen or sixteen days they might survive.

Experimental Measles.—Dr. FRANCIS G. BLAKE of New York presented this paper. He stated that with the hope of ultimately developing a method of prophylactic inoculation against measles a study of experimental measles in monkeys was being conducted. Monkeys inoculated intratracheally with nasopharyngeal washings from early cases of measles reacted after an incubation period of from seven to ten days with a group of symptoms closely resembling measles in man. These symptoms were conjunctivitis, Koplik spots, exanthem, fever, and leucopenia. The experimental disease had been transmitted from monkey to monkey by blood, skin and mucous membrane emulsions, nasopharyngeal secretions and by contact infection. Monkeys that had recovered were immune to a second inoculation. The histological lesions of the skin and buccal mucosa were identical with those of human measles. The virus could be attenuated by repeated blood passage or by preservation in glycerol so that it would produce a local and not a general infection in monkeys in intracutaneous injection.

Dr. JOHN F. ANDERSON of New Brunswick said it was just nine years since they had presented their work on experimental measles. Dr. Blake and his colleagues had repeated and confirmed their work. However, there were some phases of the subject not reported upon by Dr. Blake as, for instance, the period of infectiveness of the secretions of the nose and throat. Dr. Anderson said that the period of quarantine had been revised. They had also reported that the filterable virus could be attenuated by repeated blood passages. It had been said that their evidence of having produced measles experimentally in monkeys was not conclusive because they had not mentioned the Koplik spots. It was true they had not mentioned the Koplik spots, but they had reported on the skin lesions and on the leucopenia.

Dr. CHARLES HERRMANN of New York said that although Anderson and Goldberg, Hektoen and others had already proven that the nasal discharges and the blood of patients with measles were infectious, Dr. Blake's investigations had added some new evidence and had put the subject upon a still firmer basis. Many years ago he became convinced that with their present method, the spread of measles could not be controlled, and that such a control was only possible by means of a method of immunization against the disease, applied in early infancy. In 1913 he began to immunize infants, the method being based upon the following facts. First, the infectious material was contained in an active form in the nasal mucus at the beginning of the stage of invasion, that was just before and when the eruption was beginning to appear; second, in the large cities where practically all the mothers had had measles, a relative immunity was conferred on the offspring which lasted about five months. This immunity was absolute during the first two months and gradually disappeared; third, the infectious material was usually conveyed from the nasal mucous membrane of the patient to the nasal mucous membrane of the individual infected. It was thought that if infants were inoculated between four and five months of age, when they still enjoyed a relative immunity, this temporary relative immunity could be converted into an immunity which would last for at least a few years. This would be a distinct advantage, for almost all deaths from measles occurred in children under five years of age, principally in the second year from a complicating bronchopneumonia. With these facts in mind, the nasal mucous membrane of children with measles, who were free from other diseases, at the beginning of the appearance of the eruption, was collected on small swabs, or drawn into capillary tubes

which were sealed. This mucus was applied by touching the mucous membrane of healthy infants between four and five months of age. Up to date 150 inoculations had been made. Of these 25 infants were definitely known to have been intimately exposed to infection, and of these only two had contracted the disease. When we remembered that about 97 per cent. of all infants over five months of age were susceptible to infection with measles, it seemed that the results were pretty conclusive. It might be objected that the material used was not free from other bacteria. In practice this was not found important, as no unfavorable result was found in any case. The nasal mucous membrane normally harbored a large number of microorganisms. The filtrate might be used but was not uniformly active, and could not therefore be relied upon for purposes of immunization. For universal application it was necessary that we should have a method of preserving the virus. The addition of glycerol might answer the purpose, remembering, as Dr. Blake had shown, that by such an addition the virus became somewhat attenuated.

Dr. H. F. HELMHOLZ of Minneapolis, Minn., said he was particularly interested in the last part of Dr. Blake's paper telling about the production of active immunity. In that connection he called attention to some experiments in the Foundler Clinic in Munich. At the Foundler Clinic it was shown in 173 cases that individuals, who had been exposed to measles after being injected with 5 c.c. of blood serum taken from convalescent patients seven to fourteen days after the temperature had dropped to normal, had been absolutely protected against measles. Dr. Helmholz said they were able to report that in 10 cases where a child was in a home with an infected individual this method of immunization had been tried with apparent success. This made available a method of protecting children during the period from two to four years, the period when the mortality from measles was so extremely high.

Dr. DENNETT L. RICHARDSON of Providence said they had been making similar inoculations with the serum of convalescent patients and no child inoculated in this way had developed measles. They hoped to publish this work a little later.

Dr. BLAKE, in closing the discussion, stated that they had made detailed studies as to the infectivity of the measles virus. They had never failed to transmit the disease to monkeys when the secretion was taken in the prodromal stage, and the secretion taken on the first day always produced measles and in many instances when taken on the second day. The reason for their going into the work as to the susceptibility of monkeys to measles was not because they were doubtful of the work of Anderson and Goldberg but to clear the work of any subsequent doubt. The principal thing they felt was required was the demonstration of the pathology. The pathology of measles was not accurately worked up at the time Goldberg and Anderson did their work.

Preventive Diphtheria Work in the Public Schools of New York City.—Dr. ABRAHAM ZINGHER of New York made this presentation, in which he reported that since February, 1921, more than 50,000 school children had been Schick-tested in New York City. Children found susceptible had been immunized with toxin antitoxin. Results showed great variability in susceptibility in different groups of school children. In schools attended by the children of the more well-to-do, a much higher proportion of susceptible children had been found than in schools attended by children of the poorer classes. This striking difference could be noted from the results in two different schools; 58.8 per cent. positive in one as compared with 15 per cent. positive in another, a ratio of 3.5 to one. Relative segregation of children from wealthy homes on the one hand, excessive crowding and frequent exposure to diphtheria in the poorer homes on the other hand, explained the results. Heredity seemed to be an important factor. The control test with heated toxin had been found essential in clearly identifying the pseudoreactions which were relatively frequent in children of school age.

Dr. CHARLES HERRMAN congratulated Dr. Zingher on what he had accomplished in a comparatively short time. Owing to his repeated demonstration before the larger medical societies, the majority of the physicians in New York City were familiar with the value of the use of the toxin-antitoxin mixture in the immunization against diphtheria. Dr. Zingher had demonstrated statistically that the children in crowded districts were less susceptible because they had been immunized by exposure. This principle had long been recognized in other diseases, for example, in the marked susceptibility of the Indian and Esquimau to tuverculosis infection, when he migrated to large centers of population, in the rapid and progressive course of tuberculosis in infants, in the susceptibility of recruits from rural districts to the communicable diseases of childhood. It was therefore not an unmixed blessing to protect the child against all exposure to infection. What we desired was immunity against disease, for the prevention of exposure to infection was impossible in large cities. In the control of the spread of the highly communicable diseases, and those in which the carriers played an important part, *early* and *universal* immunization were essential. The control of smallpox was due to the fact that practically *all infants* had been vaccinated. The campaign had been begun with the immunization of school children because that was an easy and controllable point of attack. After physicians and laymen were convinced of its value, there would be less difficulty in immunizing all infants. Education was required. In his private practice, Dr. Herrman said, only 10 per cent. of the mothers immediately recognized its value and were glad to have their babies immunized. In addition 10 per cent. consented after a little explanation and persuasion, but there remained a large number who preferred to wait. Some said frankly that they did not believe in vaccination but had it done because a child could not be admitted to school without a vaccination certificate. There was still a large number of believers in the various cults who were antivaccinationists, antivivisectionists and antiimmunizationists. Possibly some day a certificate of immunization against diphtheria would be necessary for admission into school, so that all the conscientious objectors would be brought into the fold.

Dr. EVERETT W. GOULD of New York said it was quite possible and even probable that in the near future the disease diphtheria would be just as fully under the control of the medical profession as smallpox was today. The medical profession accepted the contention that the Schick test gave accurate information as to susceptibility to diphtheria and that toxin antitoxin conferred immunity. Dr. Gould then related his experience with the Schick test at St. Luke's Hospital where for the past seven years they had applied the Schick test to all children who entered the medical or surgical wards of the hospital. During the time they had had but three or four cases of diphtheria, and there was good reason to believe that mistakes in technique could explain these. In severe cases of tonsillitis that resembled diphtheria it was always advisable to give antitoxin, not because one did not have faith in the Schick test, but because a slip might have been made in the technique or the reading of the reaction.

Dr. JOHN M. DODSON of Chicago observed that there was one thing that stood out conspicuously and that was the rapidity with which the efficiency of antitoxin diminished as the days went by following the onset of diphtheria, thus showing the importance of getting the cases on the first day. The parents should be educated, and the movement for a closer cooperation between educators and the medical profession should be furthered. Forty-two states now had combined committees composed of members of the state medical societies and members of the teachers' associations. That offered an army of 500 physicians and teachers who might be utilized to spread the propaganda of early diagnosis and early treatment in diphtheria.

Dr. BOWERS of the Philadelphia Board of Health related some of his experiences with the Schick test and recommended Renner's test as giving more constant and reliable results than the Schick test.

Dr. E. H. PLACE of Boston stated that his experience agreed with that of Dr. Zingher as to the value of the Schick test. He mentioned that the Schick test might also be used for diagnostic purposes in very mild cases though he hesitated to speak of it as there might be some danger involved. For instance, in a boy who had had his tonsils and adenoids removed a month previous-

ly, symptoms resembling diphtheria had appeared. The Schick test was positive showing that he did not have diphtheria.

Dr. ZINGHER, in closing the discussion, warned against the use of the toxin antitoxin as a curative agent. This was a dangerous thing to do for the toxin antitoxin did not cure diphtheria and immunity did not develop until two or three months later.

Experience in More Than One Hundred Cases of Encephalitis in Children.—Dr. JOSEPHINE B. NEAL of New York presented this paper in which she gave a brief résumé of the literature relating to epidemic encephalitis. In this series of cases there were 50 per cent. more males than females; the same was true of epidemic meningitis and poliomyelitis. The seasonal distribution showed the maximum number of cases in the first quarter of the year; meningitis was more prevalent in April, May, and June, and poliomyelitis in the summer months. In only one instance were there two cases in the same family, and these two became ill on the same day. The mortality of the cases under 15 years of age was 28.14; the mortality of those over 15 years of age was 27.54 per cent. The most prominent symptoms were fever, vomiting, headache, malaise, and symptoms referable to the nervous system. Some patients were drowsy, some were delirious. In some instances there were ocular disturbances: diplopia, blurring of the vision, strabismus, nystagmus, convulsive movements of the eyeball, etc. The cranial nerves were most often affected. Catatonia was not infrequent. Kernig's sign was not common unless associated with spasticity. Prolonged cases were less common in children than in adults. Pneumonia was the most dangerous complication. The spinal fluid findings were practically the same as those in poliomyelitis. The cell counts might be normal but usually were from 100 to 150. In one case in this series they ran to 1500. There might be a slight increase in albumin and globulin. At the present time we must feel that the etiological factor had not been definitely established. The most common conditions from which it must be differentiated were tuberculous meningitis, brain abscess, brain tumor, and poliomyelitis of the encephalic type. The most common sequelæ were weakness and paralyses. In this series there were sequelæ in 8 adults and in 4 children. Changes in the speech and in mentality were observed in 3 adults and in 10 children.

Paralysis in Children Due to the Bite of Wood Ticks.—Dr. PETER D. MCCORMACK of Spokane, Wash., read this paper in which he said that the bite of the wood-tick, usually the Dermacentor, was occasionally followed by paralysis. The paralysis might be so extensive as to involve the whole body. It was usually progressive in type, unless the tick were removed. In fatal cases death resulted from respiratory paralysis. Removal of the tick was followed by rapid and complete recovery. With but one exception all the reported cases in humans had occurred in children. Paralysis had been constantly produced in animals by the bites of the Dermacentor venustus. The writer reported several cases and reviewed the available literature.

Third Day—Friday, June 10.

Visualizing the Child's Physical Condition: A Method Especially Adapted to Preventive Work.—CHARLES E. CARTER of Los Angeles made this presentation, which consisted in a method of charting the physical findings comparable to a roentgen ray picture as a basis for corrective work. The charts provided for a periodical health picture which constituted an index of the progress attained. The examination of only the sick child was antiquated and tended toward physical deterioration. This visualizing method was productive of practical results and permitted of any elaboration or adaptation desired. Some such system was very essential for intelligent inspection of the socalled well child. The cards contained the following headings on the left-hand margin with sufficient space allowed to tabulate the findings under each: Nutrition, teeth, adenoids, tonsils, chest, abdomen, posture, liver, extremities, appearance, symptoms, rating. Six charts were exhibited demonstrating the graphic interrelation of etiology and symptomatology in rickets, scoliosis, focal infection, nutritional unbalance, and illustrating the method of charting the first and subsequent examinations. In the course of his talk Dr. Carter stated that he understood that a hemoglobin index of 80 per cent. was considered normal in the Eastern cities; in California this was not the case, the normal there being from 90 to 100 per cent.

Dr. C. L. LOWRNAN of Los Angeles said that if an orthopedist might be permitted to speak he would like to say that he had cooperated with Dr. Carter and would like to emphasize what had been said, namely, that many children who came to them supposedly well were not well from the developmental standpoint. They might be perfectly fine, healthy looking children, but might have some orthopedic defect which potentially was fraught with great evil, as the child shown in the picture, who looked perfectly healthy, but whose ankles were slightly turned in. When he examined that child he had an *x*-ray picture of the wrist taken according to Rotch, in order to study the development of the bones in the wrist. This showed that the child was six months behind the normal child in respect to the development of his bony skeleton. He sent that child to Dr. Carter, who found that the boy was not getting proper diet; his chubbiness simply represented an unhealthy amount of fat.

Dr. FRITZ B. TALBOT of Boston considered the charts very interesting, and said they emphasized the importance which was becoming more and more apparent of studying the child and finding defects if they were present before any real harm was done. He thought it was an advantage to have before the eyes of the examiner all the points that were to be taken into consideration, though the careful man was accustomed to examine the child in reference to all those points; however, even the most careful man might occasionally overlook some point and with such a chart one could be sure that the records were complete. All were familiar with the advantage of having complete records for reference in subsequent visits that would call attention to the part of the body that was at fault. He had not had the opportunity to study the charts in detail, but in any such mechanical aid it was well to remember that the general impression of the investigator should hold a prominent place in the records. He thought there was danger in putting down individual data or forgetting that one must consider the child as a whole, while he concentrated his attention on the feature which was at fault. It was equally important to have an impression of the child as a whole. There was one other thing that should be commented on, that was that today we have no normal standards. The standards of normality must be thoroughly classified before we could be sure we were all talking about the same thing. For example, any one could tell whether teeth were carious or not, but no group of pediatrists could tell whether a child was normal in respect to height and weight. There would be a great deal of discussion as to whether he was normal or not.

Dr. GEORGE E. BAXTER of Chicago congratulated the section on having had its attention called to two things. First, he spoke of the importance of the socalled normal or well child, because he believed most of those working with children as well as those doing general work had failed in that regard. The child was usually only looked upon as a sick child. In order to accomplish something for the well child it was necessary to follow up some sort of a system similar to that Dr. Carter had outlined. It was an interesting method because it had the advantage of visualizing the condition the examiner should know about. It had value in that when the child returned to the office one could see what the condition was at the previous examination. True enough, many men made careful examinations and recorded the results, but not in such an understandable form as this. He felt that these charts were a very distinct contribution to the handling of the well child.

Dr. CARTER, in closing the discussion, said that in reference to Dr. Talbot's remark that there were no normal standards at present, it was with the hope of getting something that might be helpful that he had been keeping these records for the past three years. In California children showed greater height and weight than children in the East if Bowditch's standard of twenty-five years

ago were taken as a basis for comparison. There was the danger of these charts becoming mechanical, but he thought it was thoroughly understood that they were kept in this way only for reference. Dr. Kerley's suggestion in reference to the hemoglobin was of interest. He had said that he considered a hemoglobin of 80 per cent. normal; it was not normal in California, where there were many children with a hemoglobin percentage of 90 to 100. Dr. Carter had called attention to the difference in certain standards in California as compared with those in the East, and he supposed that if some one investigated standards, say in Colorado, they would be found to be different both from those in California and those in the East.

The Food Requirements of the New-Born Infant.—Dr. HAROLD K. FABER of San Francisco, Cal., read this paper, in which he contended that the colostrum intake of the infant during the first two or three days of life was wholly insufficient to supply the needs of the child. The colostrum furnished a scant food supply in consequence of civilized conditions. The respiratory quotient in the new-born showed that the metabolic processes soon exhausted the stored food and body protein, and at this time acidosis was not uncommon. In a series of 85 new-born children complemental feeding was carried out with a suitable modification of cows' milk in quantities limited only by the infant's appetite in order to establish, if possible, standards for maximum food requirement during the early days of life. The formula employed called for certified cows' milk, 100 c.c.; Red Label karo, 120 c.c., and 1 per cent. barley water, 480 c.c. The formula gave percentage composition of 14 per cent. sugar; 1.3 per cent protein, and 0.3 to 0.6 per cent. fat. The corn syrup furnished a highly hydrolyzed sugar and had given no trouble from the high carbohydrate intake. He had measured the breast milk intake on the first day after birth and found it was about 50 c.c.; it then rose rather rapidly until the fourth day, when there was a very rapid rise, the total on the tenth day being 450 c.c. Under this method of feeding the average gain was 9 grams per kilo of body weight per day. Charts showed the weight curves of 112 infants and presented evidence that with this method of complemental feeding the new-born infants ran a practically ideal weight curve. The additional food was administered so as to avoid any danger of starving the infant, on the one hand, and of lowering the secretory activity of the mother's breast on the other hand.

Dr. FRITZ B. TALBOT of Boston emphasized one point which he said was well brought out in the paper, namely, the importance of fluid to the new-born infant. When one depended upon the breast milk alone the infant did not get enough fluid, and unless the nurse and attendants were specially trained the fluid intake of the infant was neglected. Dr. Faber had also brought out the fact that socalled inanition fever sometimes resulted from too little fluid. The loss of weight in the new-born was of two kinds; one was mechanical, as the loss of meconium and urine, and the other was because the baby was burning up part of his body tissue to keep himself warm. It was with that idea that Dr. Faber was giving the additional food during the first few days of life, and physiologically he was quite justified in doing so, but one could not give any kind of a formula to a new-born infant and especially dangerous were high fats with whole milk. With this glucose he had seen no trouble, but he had seen trouble from formulas with relatively high amounts of fat. It must be borne in mind that when one figured up the calories per unit of body weight two factors came in for consideration, one was the amount of active protoplasmic tissue which was forming the heat, and the other was the part of the body which weighed equally with the muscle and organs, that was the fat and water. Most new babies had relatively the same amount of protoplasmic tissue (at least that assumption had not been controverted), but some infants were born fat and some were born thin, and it was not fair to give the same amount of calories to both the fat and the thin baby because the fat was inert and did not form a part in the basal heat production. Fat babies could get along on fewer calories than thin babies, and some premature babies required even more calories per kilo body weight than the average new-born infant, so why should there not be this difference in new-born infants.

Dr. BERTHA VAN HOOSEN of Chicago said she had been interested in trying to supply a more adequate amount of milk during the first few days of life without lessening the secretory function of the breast. She had assembled a milking machine, which consisted of an electric pump, which could be used on both breasts at the same time. They had used it in this way. Every six hours the pump was applied to both breasts, with the idea of opening up the milk ducts. It was also a sure cure for inverted nipples. It was applied for five minutes and the baby was then put to the breast. After the first day, when the baby had nursed, the pump was applied and the breast thoroughly emptied. The mothers all had Wassermann tests. After the third day they usually had a larger supply of milk than was required for their babies—frequently 2 or 3 ounces more than the baby could take. This milk was used for other babies on the first day after birth. This was an ideal plan; since the mothers were all Wassermann-proof there was no hesitancy in using the milk for other babies. The point to be emphasized was not so much the little device for removing the milk, but the fact that with some sentiment or practicality, whichever one wished to call it, the mothers could supply more milk than their own babies required without any trouble, and in this way one could have mother's milk to distribute to babies that needed it rather than cow's milk.

Dr. HARRY LOWENBURG of Philadelphia expressed fear lest the giving of the extra milk in the early days of life might encourage the bottle habit. Even if it had a physiological basis he questioned the advisability of giving this form of nourishment. The fault lay in a lack of water, and this could be made up in the form of water or glucose without presenting the bottle. He had found that once an infant received the rubber nipple it was difficult to keep it on the breast. He thought they should be slow to adopt this method of giving extra nourishment to new-born infants. Furthermore, he did not see just why we should try to prevent the initial loss in weight, as in spite of that loss children thrived and developed normally. It would be far safer to find a different method rather than to present the bottle. After all their propaganda in favor of breast feeding, if they now advocated this method they might find themselves in a serious predicament.

Dr. LEWIS WEBB HILL of Boston agreed with Dr. Lowenburg that Dr. Faber's paper gave the impression that the Lord had made a mistake when he planned that the new-born baby should not eat. The new-born baby was not meant to take much into its body. The colostrum was a concentrated food that met the new-born infant's needs. It was high in protein and low in sugar and one was flying in the face of nature when he attempted to do differently. He did not believe the extra food was an advantage and that the reason little breast milk was furnished was because the intestine was becoming infected with the ordinary bacteria and if it was flooded with extra food a great deal of harm might be done. Czerny thought it was even inadvisable to give sugar and advised only water. Dr. Faber said his babies had been slow in recovering their birth weight. Were they fed at four hour intervals? If that was the feeding interval it might be that if they were fed oftener they would have regained their weight more quickly. Many had tried to prevent the initial loss of weight, but the only research on this subject was made by Schick who claimed to have prevented loss of weight after birth by feeding breast milk from another woman.

Dr. J. I. DURAND of Seattle, Wash., said that the Lord when he made the plan had in mind a less highly developed nervous system than they were dealing with today. The mothers underwent very much less disturbance among primitive peoples than under the conditions of civilization. He thought that Dr. Faber had answered the criticism that had been brought by the fact that his 90 babies had done so well. As to the question whether this complementary feeding would interfere with normal breast feeding, he thought the opposite would occur. The increased vitality and strength of the baby that received the additional food

would enable it to bring the breast milk up to its requirements better if it had had complementary feeding. Dr. Durand asked Dr. Faber whether he had seen inanition fever in any of these cases.

Dr. ROGER H. DENNETT of New York said he felt that they ought to be very grateful to Dr. Faber for this paper. He had always said that babies should not have even water for the first three days of life, and he had conscientiously believed it, but Dr. Faber had seen these cases and no one had repeated the work so it hardly seemed that they ought to criticize observations which they had failed to make themselves. He asked whether there was any febrile or other disturbance in these babies. He did not understand what percentage of these babies had gone on and been entirely breast-fed; he would like to know something on that point. So far as the caloric requirements were concerned there had been no question for a number of years that babies of different nutritional standards required different numbers of calories. He had believed that the average baby needed 50 to 55 calories per pound; the undernourished baby needed from 60 to 65 calories per pound, and the fat baby required from 40 to 45 calories per pound.

Dr. FABER, in closing the discussion, said his purpose in presenting the paper was not to advocate a particular method of feeding but to report the results in this series of cases. It was perfectly true that the weight standard of feeding was faulty and so was the method of feeding by body surface. The food demand arose from the amount of activity of the active protoplasm and of that we knew the measure. He believed the only standard by which one could adequately feed a child was by appetite, and that was the method nature used. Dr. Lowenburg claimed that the fluids were enough; in his experience the fluids were not enough. In a long series of cases when given all the water they would take the babies did not do so well. The religious arguments he acknowledged were difficult to answer, but he could say that man as a civilized animal had a certain number of maladaptations and these maladaptations occurred in nature. Of this inguinal hernia was a sample; that occurred when man assumed the erect pocture and nature had not provided proper mechanical support. We could say that nature certainly had not provided enough fluids. They had lost no babies in this series except one that died of birth injuries. With regard to breast feeding after the babies left the hospital; they had not been able to hold 100 per cent. of breast feeding, but 65 per cent. of the babies remained on the breast while in this series the average was 66 per cent., so they certainly had not reduced the amount of breast feeding by the complement feeding during the first few days. There was only one case of inanition fever, and that baby refused all food.

The Breast and the Nursing Child.—Dr. FRANK H. RICHARDSON of Brooklyn presented this paper in which he stated that recent literature was comparatively bare of observations on the physiology of lactation, that was, in studies of the nursing of healthy babies. He therefore desired to present clinical observations made on three normal breast-fed babies during the nine or ten months each was on the breast. The conclusions based on these observations were: Appetite and thirst of the mother were automatically regulated by the demands of the child on the breast supply; decreasing demands of the baby were met by a decreasing secretion of milk by the lactating breast; this statement was based on observations during weaning and elimination of night feeding; what had been described by mothers as the "coming in" of the milk was a clinical entity, recognized or not by the individual; if long intervals were observed, the nursing baby could not be overfed. These conclusions were based not upon ward studies but upon replies to a questionnaire by nursing mothers. On the second day or thereabout the true milk rushed into the breast and this was often an extremely painful experience to the mother. An attempt was often made to check the amount of milk secreted by applying a binder and giving a cathartic. This line of treatment frequently resulted in drying up the milk. In a study of 200 cases of premature weaning only 18 were weaned after the first month. It was also a mistake to overfeed the nursing mother.

Dr. ISAAC A. ABT of Chicago called attention to the fact that physiological lactation depended upon some external forces and some internal forces. The internal forces might be described or referred to as the "coming in" of the milk. This phenomenon occurred shortly after birth when lactation began and it occurred during lactation when the breast became distended. The flow was dependent upon the internal factors of muscular activity, nervous activity, and glandular activity. It was well known that the nervous system had a considerable influence on the milk. The woman under the influence of fear or other psychological states was frequently unable to nurse her baby. Dr. Abt said he, too, had devised a milking machine and they had found that when the milking machine was first applied the mother showed fear and the supply of milk was inhibited. Finally when the woman became accustomed to the milking machine the milk would flow freely. Dairymen told him that they had the same experience with the milking machine. Now referring to the external dynamics they were dependent upon the sucking action, and this was dependent upon sucking and compression. The breast might be emptied in either way. It was probably that the baby used both suction and compression and that was the better way. They had found that it required considerable pressure, as estimated by an air gauge in the milking machine, to bring about the flow of milk. The amount of compression measured by the air gauge varied greatly under different conditions. Dr. Abt said he wished to emphasize the point that the baby was the best machine for emptying the breast and if a mechanical device was substituted it should be one that provided for both suction and compression.

Dr. CHARLES H. WAHRER of Fort Madison, Iowa, said he had been talking with old Dr. Aristotle the other day, and notwithstanding his great learning he had said, "Experience is fallacious and judgment is difficult." In a modern sense that told one how to feed a baby understandingly. He had never met a baby yet who could not stand a little starvation until he had figured out what to do. One need not be in a hurry to get a patent milking machine for he thought the baby would take care of the situation.

Dr. W. A. MULERIN of Augusta, Ga., said the free expression of opinion during this session showed the importance of having papers such as these on the program. He thought complemental feeding had come to stay because it was the most natural way of feeding a baby. It was simpe and it was practical. He had been surprised that more men had not taken up Dr. Sedgwick's method of complemental breast feeding. There were a few things that should be stressed that made for success in the use of this method. 1. Proper stimulation of the breast as advocated by Dr. Sedgwick. Put the baby on the breast and after ten minutes help the baby by compressing the breast with the fingers. 2. Get the mother's cooperation. The mother usually could and would cooperate. 3. The physician himself must be thoroughly convinced that he could succeed in establishing maternal nursing, and then it was easy work. It was surprising how often one would be successful in bringing up the milk supply if he carried out these three points. The practice of stuffing the nursing mother was wrong in principle and wrong in practice.

Dr. RICHARDSON, in closing the discussion, said he was glad Dr. Abt had brought out the point that the original inflow of milk was parallel to what happened a number of times a day during lactation. As to the advice derived from the quotation from Aristotle, it was good up to a certain point. It was true that a great many babies if left alone would get up an appetite, but there were babies in which the lack of food had led to inanition fever and they had no appetite. What Dr. Mulherin had said in regard to complemental feeding should be emphasized. Complemental feeding was based upon the assumption that the baby would not overfeed on the breast if fed at sufficiently long intervals, and if the baby was not getting enough food he might be fed after he had exhausted the breast supply. As to the length of the time consumed in nursing, he thought it did not harm if the baby were allowed to take forty or fifty minutes in nursing, as he was not eating during all that time.

Some Neglected Practical Points in the Technique of Infant Feeding.—Dr. JOSEPH BRENNEMANN of Chicago read this paper, in which he said that the things to which he would direct attention were so simple and elementary that except for the fact that they were of great importance they would be unappreciated or ignored. It was often the very simple things that determined whether a child was normal, happy, and mannerly or abnormal, unhappy, and ornery. Frequently when a mother had been a good breast feeder and it came time to wean the baby the child would not take the bottle. The mother may have abandoned breast feeding while she was making the attempt to have the baby take the bottle and with the baby getting insufficient food from either the breast or the bottle he might be losing weight. The mother might then try feeding the baby with the spoon, from a cup, from a hygeia bottle, etc., only to find that the baby rejected all these means of obtaining nourishment. The situation was then difficult indeed. It was not the food that the child objected to, but the method. The psychology of habit explained the situation. The baby preferred one food by one method; monotony did not pall upon him. A difficult situation of this kind could easily be avoided by teaching the baby very early in life to take the bottle. This might be done without interfering with breast feeding, by giving a little slightly sweetened water in the bottle after breast feeding. If there was any objection to giving the small amount of sugar in the water a little saccharine might be added. Even in the second year the baby as a rule would not take as much from a cup as from a bottle. He saw no reason of depriving the child of the bottle and thought the child should be allowed to have the bottle well into the second and even into the third year. The same psychology applied in reference to spoon food. Spoon food in the form of strained vegetables might be given as early as the fifth month. If attention were given to these matters there would be no difficulty in passing from the breast to the bottle and from one kind of food to another. This apparently simple matter might have an influence on the child's entire attitude toward life. The child who would not take the bottle, refused the cup, the spoon, and every feeding device, and whose mother spent hours trying to cajole him into taking each new article of food, was liable to become the person with peculiar tastes, who could not eat this, that or the other article of food, and adapted himself poorly to all situations in life.

Dr. BORDEN S. VEEDER of St. Louis said he was much gratified to hear this paper. They now started early to feed babies with cereals and vegetables. He had done nothing in recent years that had given him so much satisfaction as starting in early with spoon feeding. He started at five months giving cereals and at seven months gave strained vegetables. He did not believe in starting with the bottle too early. Neither did he believe in the child having the bottle for two or three years, as he could see no necessity for it.

Dr. MARY T. MOORE of Boston called attention to the importance of making sure that the baby was not tongue-tied when it did not take the bottle readily. Such a child might be looked upon as cantankerous when the difficulty was a mechanical one.

Dr. H. M. APPEL of New York stated that they encouraged spoon feeding at the hospital with which he was connected, but they dreaded the use of sugar because they had seen it cause eczema and green stools. Spoon feeding early placed one in a position to overcome any deficiency in the diet during the first year. They started with one teaspoonful of cereal a day and changed the variety of cereal each day. They instructed the mothers how to prepare the cereal and it was forced down if necessary, as though it were medicine. In this way the child soon became adjusted to the spoon.

Dr. E. J. HEUNEKENS of Minneapolis said they fed solid food after the sixth month and from the tenth month on the baby used a cup and solid food and they went one step further. The babies were put on three meals a day when they were ten months old. This made the care of babies much simpler. They had carried out this plan for five years with a large number of babies.

Dr. M. L. TURNER of Des Moines said he wished to indorse the three meals a day plan. The children did better on three than on five meals a day. They had one child fed on three meals a day that weighed thirty pounds at the age of two years.

Dr. BRENNEMANN, in closing the discussion, said he first began giving vegetables and cereals to children ten months of age, and then gradually worked down to nine, to eight, to seven, to six, and now to five months. He began when the baby was five months old with cereal and when it was six months old vegetables were given. Until ten years ago he had followed the teachings in the books and took the babies off the bottle at the age of thirteen months and put them on the cup. In his experience it was wholly unsatisfactory. During the last ten years he had done the opposite, and allowed the child to have the bottle until the fourth year. In his experience it was not true that a baby in the second year would take as much milk as he wanted it to take. As to giving water in a bottle, he did not give much sugar in the water. He only gave an ounce of water and very little sugar. As to the three meals a day, he recalled having read a book on children written sixty years ago in which three meals a day were advocated at the latter part of the first year. He had never been able to feed a baby successfully on three meals a day, though perhaps it might be done, as many babies could perform quite remarkable dietetic acrobatic stunts. During the latter part of the first year and the second year he preferred to give five meals a day. Three meals might be given at the end of the second year, but he thought it a little difficult for children to get along well on three meals a day much earlier.

Diet as a Factor in the Etiology of Adenoids.—Dr. FRANK VANDER BOGERT of Schenectady, N. Y., presented this contribution. He stated that little was known of the cause of adenoids and tonsillar hypertrophies, and therefore there was little opportunity for their prevention. Their frequent association with rickets suggested that the same underlying etiological factor might be responsible for both conditions. There was considerable evidence to indicate the dietetic etiology of rickets. It was also quite generally recognized that adenoid and tonsil hypertrophy were associated with digestive disturbances in later childhood. These digestive disturbances frequently persisted after the removal of the tonsils and adenoids. Carbohydrate excess frequently was responsible for a catarrhal condition of the digestive tract extending from the mouth to the anus. It was reasonable to believe that such a condition might also involve adenoid and tonsillar tissue. Tissue thus affected was lowered in resistance and fell an easy prey to infection. It was worthy of note that the development of adenoids and hypertrophied tonsils was coincident with the introduction of bottle feeding at the end of the first year. Hypertrophied tonsils and adenoids were frequently found associated with colitis, mucous disease, and enuresis. Of a series of 101 infants artificially fed, sixty-one showed hypertrophied tonsils, and of sixty-five children breast fed for more than one year fifty-one showed enlarged tonsils and adenoids, indicating that there might be some relation between the prolonged nursing and the hypertrophied tonsils. A sufficiently large number of cases were treated dietetically by restriction of carbohydrates following the removal of tonsils and adenoids to afford a basis for the belief that diet had an influence on the recurrence of tonsil and adenoid growth. Bad hygiene seemed not to be a factor in the causation of adenoids, for in China, where hygienic conditions were notably bad, hypertrophied adenoids and tonsils were rare. The facts seemed to point to the increased consumption of sugar and the unbalanced ration as an etiological factor in tonsil and adenoid hypertrophies.

Regional Sensitivity of the Skin of Normal Infants.—Dr. LOUIS W. SAUER of Evanston, Ill., presented this paper, in which he described a number of attempts that had been made to perfect tests whereby the exudative diathesis might be detected in its latent side. None of these investigators used the same substance on the various regions of the body. The thorax, feet, and palms were seldom involved in infantile eczema. The face and buttocks were the sites of predilection. Solutions of phenol in benzol were applied to the cheeks, buttocks, thorax, and sole of 100 normal-skinned infants. The reaction one hour after the application and twenty-four hours later were compared. The phenol benzol

was applied in strengths of 15, 20, and 25 per cent. to the above mentioned sites. At the end of one hour the 15 per cent. solution gave seventy-seven reactions on the cheek, twenty-four on the chest, and seventy-one on the buttocks; at the end of twenty-four hours there were twenty-seven reactions on the cheek, three on the chest, and twenty-six on the buttock. Using the 20 per cent. solution, the cheek showed ninety-seven positive reactions, the chest forty-four, and the buttocks eighty-five; at the end of twenty-four hours the 20 per cent. solution gave fifty-nine positive reactions on the cheek, seven on the chest, and forty-seven on the buttock. With the 25 per cent. solution at the end of one hour the cheek gave ninety-eight positive reactions, the chest sixty-five, and the buttock eighty-eight; at the end of twenty-four hours the cheek showed seventy-eight positive reactions, the chest twenty-one, and the buttock fifty-nine. From these results it was evident that the regional difference in the skin must be reckoned with in perfecting tests for the exudative diathesis.

The Clinical Diagnosis of Heredosyphilis.—Dr. HENRY F. STOLL of Hartford read this paper in which he stated that the Wassermann test was frequently negative in late heredosyphilis. There were, however, often certain "leads" in the symptomatology and careful examination would frequently reveal suggestive physical signs. The cases reported showed that the chief "leads" might be found in other members of the family. If with care and patience one fitted together these isolated and in themselves apparently insignificant data, he would frequently obtain an unmistakable picture of familial syphilis.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 3, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

Concerning the Function of Calcium in Plant Nutrition.—Professor RODNEY H. TRUE, Director of the Department of Botany of the University of Pennsylvania, delivered this address which was illustrated by lantern slides. He stated that the investigation upon which his presentation was based was begun ten years ago in order to determine, if possible, the reason why distilled water was injurious to plant life. In making the investigations new methods of determining the behavior of plants in distilled water were employed. A study was made of the interchange of substances between the plant and the solution. The method of measuring the interchange by the varying resistance of the solutions to the electric current had enabled them to make much more accurate estimations than was possible by ordinary chemical methods. When seedlings were placed in distilled water the conductivity of the water was found to be increased which meant that something was being given off by the plant. The conductivity of the water continued to increase for some time but later came to a state of equilibrium. An attempt was made to find out whether distilled water was harmful to plants because of something in the water or whether it was because there was nothing or nearly nothing in it. The water was purified in many different ways without any apparent difference being noted, and they finally reached the conclusion that distilled water was harmful to plants because it lacked something. They then tried to grow plants in solutions of distilled water containing minute amounts of various chemicals. If potassium chloride was added to distilled water they found that the water attained more and more a condition of purity, indicating that the plant was taking something out of the water. Other experiments showed that the changes in the solution were not due to differences in osmotic action but to differences in chemical action. Plants were grown in various solutions of alkaline salts and alkaline earths and the results observed. These experiments were carried out first with solutions containing a single salt and then with solutions containing two or three different salts. The solutions containing the salts of potassium and sodium gave results not widely departing from those of distilled water. The case was somewhat different when the alkali earths were used; here absorption took place. A marked absorption took place in the weaker solutions of magnesium salts, but when this salt was added in any considerable quantities the plant became poisoned and died. The addition of calcium salts to distilled water was tried, and the results of these investigations indicated that the calcium salts prevented the leeching observed with other salts. It was well known that we limed land for deficiencies of the soil but the nature of this necessity had never been understood. It was thought that the function of the calcium was to neutralize the acidity of the soil and improve its character, leaving out this factor of absorption which was quite as important in plant nutrition. Plants were grown in solutions of distilled water containing different calcium salts which led to the discovery that certain groups of calcium salts were more readily absorbed than others. The sulphate, carbonate, chloride, and nitrate were about equally absorbed, and some plants absorbed more of one salt than of another. The plants that absorbed calcium sulphate most readily were the sea coast plain plants. The plants which used calcium in rather moderate amounts were the acid land plants. Garden plants used other kinds of calcium salts. The question here arose as to whether the calcium demands of animals and people could be readily supplied by these plants. This was a most important question both to agriculture and to public health. It was found that if a solution of distilled water contained more than one kind of salt the plant absorbed the salts more readily than when only one salt was present. It was also evident that in the presence of calcium other salts were absorbed more readily. This fact also had an agricultural bearing. In putting different kinds of fertilizers into soils the question of their availability had not come up for consideration. He had found that in solutions that very closely approximated soil conditions the solution might rob the plant and, similarly, not only was the soil able to yield materials to the plant, but it might even abstract materials from the plant. The question of calcium-magnesium ratio which had long been a subject of discussion among those interested in plant physiology had received overemphasis. They had found little evidence that the calcium magnesium ratio was as important as some investigators had thought it to be. So long as calcium was present its ratio to the quantity of magnesion was of little significance. When mixtures of three salts were used it was found that these were nearly complete solutions for plant growth, provided calcium was present, the evidence indicating that the function of calcium was predominant, and that if other salts were present and calcium was absent the plant structure fell apart. A plant placed in magnesium sulphate solution seemed to prosper for a time but after a time it developed pathological symptoms and went to pieces with the characteristic symptoms of magnesium poisoning. This occurred in a way that suggested a cumulative action of the magnesium upon the plant, which seemed to store magnesium until it concentrated to a sufficient extent to be fatal. There had been in the past a good deal of discussion as to whether hot lime was injurious to the plant. It seemed that they had here a hint from which they might develop a positive answer to this question. In dolomite (magnesium calcium) soil which was sufficiently rich these symptoms of magnesium poisoning seemed to develop due to an accumulation of magnesium in the plant. Absorption might be defined as the process by which materials in solution got into and attached themselves to the cells of the plant. There was a difference between plant and animal cells, both in the cell wall and in the cell contents. When in a solution the contents of the cell were separated from the solution by an osmotic membrane there must be a tendency for the solution and the cell contents to come to equilibrium. One might get an idea of the behavior of the plant cell in a calcium free solution. In such a solution there was a tendency for the outer tissues of the cell to fall off and settle to the bottom of the solution. It had been found that these tissues were still living. They parted from the plant for some reason that should be explained. This subject had been investigated and it was found that the cell walls consisted of two layers over a thin wall, mostly cellulose; between these

layers was a thickened lamella belonging to both adjoining layers. This lamella was not cellulose but was a compound of calcium with pectic acid, a substance known as pectate. It had a great deal of strength and held plant tissues together. Pectic acid and magnesium formed a compound of considerable firmness but not at all as strong as the compound formed by pectic acid and calcium. If calcium was not present we had a magnesium or potassium pectate substance that readily fell to pieces. A plant in a calcium short solution would have a sloughing epidermis and a fusing out of calcium ions. One investigator had worked out the amount of calcium necessary to protect a grain of wheat. When the calcium ions began to ooze out other substances came out also, such as magnesium, sugar, and amino acids, and something far reaching happened at once. Copper sulphate had been shown to be a deadly poison readily absorbed by plants when calcium was not present; calcium very much delayed the permeability of the plant to copper sulphate. The amount of pectate in a plant increased with the age of the plant. It formed on the outside of the cell wall and seemed to come from the interior of the cell. The cell perhaps extruded the substances of which the lamella was composed in a definite order and only when they were all present was calcium pectate formed. This was probably the result of light action dealing with the substances of the cell. The speaker then drew an analogy between this function of calcium in plant life and the findings of Herbst in his study of sea-urchins. Herbst had found that when sea-urchins were deprived of calcium various types of malformation resulted and that they showed a marked tendency to fall to pieces because of lack of coherence. Another observation was that the H_2SO_4 ion seemed to prevent the absorption of other ions. Iron was of use in connection with the chlorophil function, and while its function here was not understood it was not a decisive factor in absorption in these plant studies. It seemed clear that the deeper lying aspects of this subject required further investigation. In order that such investigations into the physiochemistry of plants might be carried out there was need of an apparatus which would make more accurate measurements than any they had at present.

The Calcium Requirement in Animal Nutrition.—Professor H. C. SHERMAN, in discussing this phase of the subject, said that all the while he was listening to Professor True unfold the function of calcium in plant nutrition he had been wishing that they had the information to draw a parallel for the animal and particularly for the human organism. Speaking of only a few observations relative to the function of calcium in animal nutrition, mainly from the standpoint of gross results, it might be mentioned that Osborne and Mendel described experiments in which they fed growing rats with a ration otherwise adequate but in which they reduced to the minimum each in turn several of the inorganic constituents of the food. The outstanding result was that while the animals got along very well on small amounts of sodium, or of potassium, or of chlorine, they required very considerable amounts of calcium and of phosphorus. With reduced amounts of calcium the growth stopped more quickly in some than in others. Aron and Sebauer made somewhat similar experiments on dogs and found that when calcium was withheld from the diet some of the dogs stopped growing, while one dog grew as well as the control. Aron and Sebauer made a chemical analysis of the bones of dogs fed on a calcium-poor diet and found that they contained less mineral matter than the bones of control dogs. Van Gieson was interested in the effect of a calcium-poor diet on tuberculosis. He found a much greater resistance in the dogs having a calcium-rich diet, and a low resistance and great susceptibility in the dogs having a calcium-poor diet. It was altogether probable that these instances and many others in which results had been attributed to a deficiency in the mineral elements were more or less influenced by a deficiency in vitamines as well. Van Gieson's diet poor in calcium must have been poor also in the fat soluble vitamine. Mendel had spoken of the fact that animals on a calcium-poor diet maintained their nitrogen equilibrium and showed no effect due to the loss of lime for a long time, but then they suddenly underwent collapse. McCollum also had pointed out from his experiments that a ration consisting largely of seeds was deficient not only in calcium but also in sodium and chlorine and in the fat soluble vitamines. This deficiency might be remedied by the addition of the leaves of plants, milk and eggs which afforded protection against a diet consisting of seeds, while meats, fats, or sweets never made up the deficiency. Diets deficient in calcium as well as in fat soluble vitamine were believed to be relatively common, and such nutritional deficiencies might be important factors in susceptibility to infection. From the practical standpoint of human nutrition they had been interested in the question as to whether in the typical American diet there was any appreciable danger of calcium deficiency. A comparative study had been made of the diets of over 200 families, covering definitely the food intake and the results compared with about 100 laboratory experiments upon the requirements for normal calcium equilibrium. On comparing the two sets of data it appeared that about 16 per cent. of typical American diets were distinctly deficient in calcium. Some of these individuals did not get enough food. Figuring on a basis of 3,000 calories a day as a normal intake it seemed that about 7 per cent., or one in 14, were getting a diet deficient in calcium. The question came up whether this deficiency in calcium could be made up in the drinking water. He thought that in general we could not trust the water to do more than replace the calcium lost in the process of cooking. If the calcium deficiency, which was perhaps the commonest deficiency in the American diet, were the sole deficiency it could be remedied by the simple addition of calcium salts but it seemed that the calcium deficiency was not the only deficiency. A series of experiments were made to study the effects of successive additions of salts to a basal ration of patent flour which showed that while this flour was particularly deficient in calcium it was also deficient in other mineral salts which were necessary in order that the calcium might be assimilated. It would not be safe to rely upon the addition of calcium alone to a diet, but we should encourage the more liberal use of foods such as milk and vegetables containing the other mineral salts and which possessed an all-around well-balanced mineral content and were important for their vitamines as well.

Dr. ALFRED F. HESS said it was impossible for one interested mainly in clinical medicine to discuss this admirable paper on plant physiology. As was well known all crops suffered from lack of calcium and this in turn had been proven by recent experiments to have its effect on animals. Dr. Hess referred to a recent report from the Wisconsin Laboratory by Hart, Steinbart and others who had performed the experiment of arranging the diets of cows so that they merely lacked calcium. As a result the calves were all premature, still-born or weakly, though all the other requirements of diet were fulfilled. Forbes of the Ohio Agricultural Station had shown that cows producing milk on a winter ration did not maintain a calcium balance. These experiments showed how important it was that the calcium requirement be fulfilled in the diets of animals. Dr. Hess said that he suspected that the diet of human beings was often deficient in calcium. We obtained our calcium from milk, eggs and vegetables and it was peculiar that some people ate very sparingly of vegetables and took very little milk, and consequently their diet was low in calcium. A number of such cases had been brought to his attention. This had been particularly true during the past few years of the peoples of Central Europe. The lack of phosphoric acid was still more common owing to the fact that they had been deprived of eggs, milk, cheese and meat. When there was a lack of calcium in the diet there might be no symptoms whatever, but among the early symptoms were little petechial hemorrhages and edema about the ankles. He had wondered as he listened to the paper whether this could be due to a phenomenon something like that described by Professor True in plants where there was a lack of calcium pectate; whether it might be due to a lack of calcium in the walls of the lymphatics which permitted exudation. Dr. Hess said he wished Dr. Sherman would

tell them what he believed was the role of the vitamines in calcium metabolism, and whether he was in agreement with the theory commonly accepted and brought forward by Mellanby, who found that the laying down of bone in dogs was associated not only with calcium in the diet but also with a vitamine. The remarks of Professor True had a close application to human pathology, and especially to rickets, which was so closely associated with the calcium problem, and to the relation of anions to the cations. He thought these were involved in the occurrence of rickets and that this work showed how impossible it would be to solve the problem of rickets from mere clinical observations.

Dr. GEORGE B. WALLACE stated that there were some interesting analogies between the facts Professor True had brought out and certain facts in animal physiology. Thus it had been shown that exudates and transudates in serous membranes could be prevented by previous administration of calcium. It was assumed from this that the chief factor in transudation and exudation was a deficiency of calcium in the vessel walls. There was a close analogy again in intestinal absorption. If the absorption of various salts was studied, it was found that one group, such as chlorides, bromides, iodides, was easily absorbed. The members of this group all formed soluble calcium salts. Another group, sulphates, tartrates, oxalates, etc., were absorbed with difficulty. The members of this group formed insoluble calcium salts. The explanation of the lack of absorption was that the calcium in the intestinal wall was precipitated, and permeability was checked as a result. Again, in line with Professor True's experiments, it was possible to induce general anesthesia in animals by giving magnesium nitrate by stomach, but not by giving magnesium sulphate.

Dr. TWEEDELL stated that he had been trying various solutions of calcium intravenously. Max Kahn said that the calcium inorganic salts were not absorbed but lately he had been using organic compounds of calcium which were very readily absorbed. These were the substances usually thrown away, the egg shells. We used the raw egg or boiled egg and threw away the shell. He found that the calcium of the shell was more readily absorbed than any of the calcium salts he knew of. He had noticed that wounds in patients with tuberculosis did not heal unless a large amount of calcium was given. Finding that calcium was a necessity for the healing of wounds he had tried to find a territory where there was no calcium and he finally learned that on the Island of Aden there was practically no calcium, that the only water they had to drink there was distilled water, and there was no vegetation, all their foods being imported. Just as he was writing to make inquiries about this island he met a merchant, recently returned, who told him that wounds did not heal in that locality and that when any one was wounded he was sent away from the island.

Dr. SHERMAN, in reply to Dr. Hess' question as to the relation of the fat soluble vitamine to the assimilation of calcium, said he had great respect for the fat soluble vitamine and believed it very important but thought it had no specific relation to the development of bone as the English work had indicated. In their little animals bone formation went on when they were receiving no fat soluble vitamine, but one always had to take into consideration the fact that we did not know the amount of fat soluble vitamine stored up in the body, which was more variable than had been recognized in experimental work.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CONNECTICUT MEDICAL EXAMINING BOARD.

November 9 and 10, 1920.

(*Continued from vol.* xcix, *p.* 989.)

HYGIENE AND MEDICAL CHEMISTRY.

1. What are the chemical changes which occur in protein, fat, and carbohydrate constituents of food as they pass through the body?

2. What is the chemistry of the red blood corpuscle?

3. Where in the body is glycogen found? What is its origin and ultimate disposition?

4. (*a*) Give a method for determining the presence of free hydrochloric acid in the stomach contents. (*b*) Quantitative estimation?

5. Give chemical tests for acetone and diacetic acid in urine.

6. Describe sea-port prophylaxis against bubonic plague.

7. Discuss prophylactic methods for control of diphtheria, including the various ways of inducing and estimating immunity to the disease.

8. Describe a sanitary dairy.

9. Describe the acceptable methods for hospital ventilation.

10. Give the required cubic air space for hospital wards for children, infants, and adults.

PRACTICE, PATHOLOGY, AND DIAGNOSIS.

1. and 2. (a) What physical signs would you expect to find in a case of left sided interlobar empyema in which the fluid (about 250 c.c.) lies mostly anterior to the mid-axillary line?

(*b*) What is the usual history of onset, the symptomatology, and the course of the disease?

(*c*) Discuss the differential diagnosis and treatment.

(*d*) At what stage would you advise thoracotomy?

3. Describe the symptoms and physical signs referable to the abdomen in some cases of spondylitis.

4. What are the important points in the differential diagnosis of ascites and a large ovarian cyst?

5. How would you treat a small, slightly indurated ulcer of the glans penis of two weeks duration?

6. In a six months old baby on a modified milk mixture, what are the characteristic symptoms and signs of (*a*) an excess of fat in the diet, and (*b*) an excess of carbohydrate?

8. Briefly define three of the following: petechiæ, pyuria choked disc, Babinski's sign.

9. and 10. Mrs. K, age 36, white, is a native of Connecticut, where she has lived on a farm all her life. She was admitted to the hospital in July and gave the following history: *Chief complaint.* Pain, which she has had at intervals for six years, in lower part of abdomen.

Present Illness. Four days ago she had cramps in the lower part of the abdomen. These she describes as tearing in character. They were accompanied by pains in the arms and legs. She had a similar attack five weeks ago and another five weeks prior to that. At the beginning of each attack she vomits, is able to retain very little food, the bowels are constipated, and she is forced in a few days to take her bed. At this time the abdomen and extremities are so tender that she suffers even from the pressure of the bed clothes. Th first attack occurred six years ago and lasted about ten days; since then these attacks have come on at increasingly shorter intervals, till now they occur about every five or six weeks. She has twice been operated upon in one of these attacks, each time without relief, once for supposed appendicitis and once for intestinal obstruction. The attacks she says are not accompanied by fever do not follow an indicretion in diet, and are not related to menstruation. Between the attacks except for constitpation the patient's health is good. She has, however, had occasional pains in her arms and legs for several years, during which time she has had increasing difficulty in extending the hands.

Past History. Has had usual children's diseases including diphtheria; no other infections or constitutional diseases except that she has always been rather nervous and easily excited. Has had no headaches or disturbances of vision, no symptoms referable to ears, cardiorespiratory, or genito-urinary systems. Habits are good.

Family History. Father died of an accident, mother of "heart failure," one sister of tuberculosis. Husband is living and well. Four years ago she had a miscarriage at four months; except for this she has never been pregnant.

Physical Examination. A poorly nourished, rather pale and nervous woman who looks ill. Skin is clear. There is a slight diffuse enlargement of the thyroid

gland. No exophthalmos. Pupils are large, equal, and react sluggishly to light and accommodation. The tongue is slightly coated, the teeth in fair condition, and the pharynx normal. Lungs normal. Heart normal except for tachycardia. (Pulse 120, regular.) Abdomen not distended, no definite tender areas on deep pressure but considerable diffuse muscle spasm throughout and marked hyperthesia in the hypogastrium on both sides. Scars of former operations in good condition. Vaginal examination negative. Extremities: There is slight tremor of the fingers and all the reflexes are exaggerated, especially those of the lower extremity. There is a definite bilateral patellar and ankle clonus. (This clonus disappeared in two days.) There is some weakness in the handgrasp on both sides and inability to completely extend the hands. Babinski's and Kernig's signs absent. Spine negative. Pulse 120 to 86. Blood pressure S. 158, D. 90. Temperature normal. Urine, 1,300 c.c. in 24 hours, clear amber, acid, sp. g. 1012, very slight trace of albumen, no sugar. Microscopic, few uric acid crystals, rare hyaline cast. Hgb. 70 per cent. R. B. C. 4, 400,000. W. B. C. 6,200.

Discuss the diagnosis. What further data do you wish in order to make your diagnosis more certain?

ANSWERS.

HYGIENE AND MEDICAL CHEMISTRY.

1. *Proteids* are digested in the stomach (by the pepsin of the gastric juice) and in the small intestine (by the trypsin of the pancreatic juice).

During digestion the proteids are split up into proteoses, peptones, polypeptides and amino-acids. The amino-acids are believed to be taken as such by the epithelial cells and carried to the blood of the portal capillaries. Another view is that in the intestinal epithelium the amino-acids are built up again into proteins such as are found in the blood. There are three theories of the further history of the proteids. According to one of them (the theory of Voit), "the protein of the tissues, living or organized protein, is to be differentiated from the absorbed circulating protein. It is only in this circulating protein, which is assumed to be present in the fluids of the body, the blood, and lymph, that catabolic changes take place. These changes take place under the influence of the living cells. The more resistant organized protein is not supposed to undergo catabolic changes. If any of it does, it is cast off into the fluids of the body, and thus becomes circulating protein, undergoing catabolic changes in precisely the same manner. It is obvious that a small part of the absorbed protein must be utilized to replace the waste of the organized protein and to subserve the process of growth. This portion is termed tissue protein."

Absorption of Proteins.—"The view previously held with regard to the absorption of protein was that during digestion protein was finally converted into peptone, and the peptone so produced was absorbed by the columnar cells over the villi, and built up again by these cells into serum albumin and serum globulin, the chief proteins of the blood plasma. The view generally accepted now is that protein is completely hydrolyzed into the cleavage products known as amino-acids in the intestine; and it is these amino-acids which, being smaller molecules than the original protein, readily pass through the striated free border of the columnar cells over the villi and so get into the protoplasm of these cells. Here a synthesis takes place, and some simple and aromatic amino-acids are converted by the columnar cells into serum albumin and serum globulin, the native proteins, and this protein is conveyed to the tissues."

Digestion of Fats.—In the stomach the gastric juice dissolves the connective tissue binding the fat cells together, and sets free the fat, which passes into the duodenum. Here the steapsin of the pancreatic juice (aided by the secretin) splits up the fats into glycerin and fatty acids.

Absorption of Fat.—"Fat is not absorbed as fat, but as glycerin and fatty acid or soap. It is generally accepted that the fatty acid set free in the intestine is dissolved by the bile salts, and in this way, together with the glycerin, is absorbed by the columnar cells, but that during absorption a lipase which is contained in the columnar cells resynthesizes, by reverse action, the glycerin and fatty acid. In this way minute fat particles are found near the bases of the columnar cells. The fat globules are further taken up from the columnar cells by some of the lymphocytes, which are capable of exhibiting ameboid movements, and which are found in the lymphoid tissue between the columnar cells and the central lacteal. The fat is then deposited in the central lacteal by these ameboid cells, and in this way it gets into the general lacteal stream, and thence into the thoracic duct. The bile salts, which have been absorbed by the columnar cells, in all probability get into the portal vein radical, and in this way are taken back to the liver to be excreted again in the bile."

Absorption of Carbohydrate.—"During digestion the greater part of the carbohydrate of the food is converted into the glucoses. These are comparatively small molecules which are readily dissolved, and easily passed through the columnar cells into the portal vein radical which lies beneath. It is possible that some maltose may be absorbed by the columnar cells, and that during its passage through those cells it is converted into dextrose before it enters the portal vein radicals. It is possible that in these columnar epithelial cells the glucose, which is being absorbed, is linked to the cell protein, and that, farther down the cells, this loosely combined substance is split into two, the dextrose passing into the portal vein radical and the protein molecule remaining intact in the columnar cells and ready to combine with fresh glucoses to be passed through the cells. A small portion of the dextrose, which is carried to the liver, goes on unchanged to the tissues to be assimilated, but the greater portion of the absorbed glucose on arriving at the liver is stored there by the liver cells as glycogen." (Lyle's *Manual of Physiology.*)

2. *Chemistry of the Red Blood Corpuscle.*—The red blood corpuscle contains from 60 to 65 per cent. of water and from 35 to 40 per cent. of solids. The latter consists of hemoglobin (which is the chief ingredient), protein, cholesterin, lecithin, and inorganic salts of potassium and sodium. The hemoglobin is the carrier of oxygen from the lungs to the tissues; it contains iron, and its molecule is very large and complex, with a high molecular weight. The oxygen is in very light chemical union with the hemoglobin, so as to be the more readily given up to the tissues; the hemoglobin thus deprived of its oxygen is called reduced hemoglobin. When it is charged with oxygen it is sometimes called oxyhemoglobin. The coloring matter is called hematin. There are compounds and derivatives of hemoglobin.

3. *Glycogen is found* in the body in the liver cells, in muscle tissue (including the heart), in the white blood corpuscles, and in the placenta.

Glycogen is chiefly *formed* from the carbohydrates. The liver cells act upon the dextrose into which the carbohydrates have been converted by the action of the ptyalin and amylopsin of the digestive juices. This *may* occur by a simple process of dehydration:

$$C_6H_{12}O_6 - H_2O = C_6H_{10}O_5$$

But the precise process by which it occurs in the liver cells is not known. At a subsequent period the glycogen is transformed into dextrose and is returned to the circulation. Hence the blood of the hepatic veins contains more sugar than the blood of the arteries, and these latter more than the blood in the veins (except the hepatic). This is the generally accepted view, but it is denied by Pavy, and the whole subject is in a state of uncertainty.

The *function of glycogen* is to form a temporary reserve supply of carbohydrate material that is stored up in the liver during digestion, and made use of between meals; at the same time the percentage of sugar in the systemic blood is kept nearly constant.

4. (a) *To determine the presence of free hydrochloric acid in the stomach content:* Dimethyl-amido-azobenzene forms a yellow solution which turns red with free mineral acids. Delicacy = 02 p/m HCl. This and other similar tests are applied by simply mixing a few drops of the indicator with a like quantity of the contents.

(b) *Quantitative estimation: "Töpfer's Method.*—Three samples of 10 c.c. each are separately titrated with N/10 NaHO solution; in (1) using phenolphthalein as an indicator, and carrying the addition of alkali to

a distinct red, not to faint pink, as is usual. This gives the total acidity (A), made up of free HCl (L), protein HCl (C), and organic acids and salts (O). In (2) alizarin is used as an indicator, to pure violet. This gives the acidity due to (L + O), and, therefore, the result of (2), subtracted from that of (1), leaves the value of (C) = protein HCl. In the third sample (3) dimethyl-amido-azobenzene is used as an indicator to yellow. This gives the value of (L) alone, *i.e.* free hydrochloric acid. If the value of (O) be desired, it may be obtained by subtracting the result of (3) from that of (2). In each of the above titrations the number of c.c. of alkaline solution used, multiplied by 0.0365, gives the result, expressed in percentage of HCl." (Witthaus' *Manual of Chemistry.*)

5. *Chemical test for acetone in the urine:* "*Legal's test* for its detection consists in the addition of a few drops of a strong solution of sodium nitroprusside to about 4 c.c. of urine which has been previously rendered alkaline by potassium hydroxide solution. In the presence of acetone a red color is produced, which turns purple on the addition of acetic acid."

Chemical test for diacetic acid in the urine: "To detect its presence the urine should be boiled with a solution of ferric chloride, and if diacetic acid is present, a Burgundy-red color will be produced." (Hughes' *Practice of Medicine.*)

6. *Seaport prophylaxis against bubonic plague:* "Passengers and crew from plague-infected ports are carefully inspected at quarantine. . . . The period of detention is seven days. The sick are isolated in the hospital and the remainder segregated in small groups. All persons exposed to the infection are bathed and their body clothing disinfected. Rats and fleas on the vessels must be killed and burned. The destruction of rats on a ship requires special knowledge and care, else many rats escape. Sulphur fumes generated by the pot method remain the cheapest, simplest, and best method yet proposed for this purpose. . . . A survey of the ship from stem to stern, from pilot-house to bilge, should be made in order that the disinfector may know its peculiarities of construction, the location of apartments, the condition of doors, ports and ventilators. Before the sulphur pots are lighted, dunnage must be piled up or slung two feet from the floor. . . . The engine-room sometimes needs treatment, and all engine-room lockers should be freely opened. Forecastle lockers, the forepeak with small manhole hatch, and its two or three lower compartments, usually stored with ropes and canvas, are favorite refuges for rats. The galley, pantry, and storerooms must not be neglected. . . . Rats are sometimes found in the dining saloon, social hall, lifeboats, rafts, the bilges, vegetable bins, refrigerating plants, and even in the casings over the steering gear. All out-of-the-way places must be carefully scrutinized after fumigation for live, dead, or dazed rats. Special precautions must be taken to prevent the escape of rats. Vessels should be anchored at sufficient distance from shore to discourage rats swimming to the land. If the vessel ties up to the dock the hawsers must be guarded with balls of tar or special traps in order to stop rats reaching the shore along these lines. Gangplanks must be taken in before dark, and searchlights will help to deter rats from leaving the ship. Nothing should be thrown overboard. . . . A plague-infected ship is given a simultaneous disinfection and the cargo is removed by a special procedure. After sulphuring, the cargo is removed piece by piece to lighters, each article being examined as it swings overboard for rat nests. This work goes on during the day, while the empty cargo spaces are fumigated with sulphur during the night." (From Rosenau's *Preventive Medicine.*)

7. *Prophylactic methods for the control of diphtheria:* This is difficult, but the following points should be tried: (1) Determination of carriers and, where possible, their isolation; (2) the application of Schick's test to all contacts and children; (3) the immunization of all susceptibles by toxin-antitoxin inoculation; (4) early recognition of the disease; (5) isolation until two or more cultures from nose and throat, at 24-hour intervals, are negative.

The Schick test is performed as follows: One-fiftieth of the minimum lethal dose of diphtheria toxin for a guinea pig is diluted to make 0.1 c.c. of fluid; this is injected intracutaneously. If there is at the site of the injection a local reaction or inflammatory area at the end of 24 hours, the subject is susceptible; if there is no such reaction, the subject is insusceptible.

8. A SANITARY DAIRY. The following items, taken from the rules of the Indiana State Board of Health, give, by implication, an idea of a sanitary dairy: "(1) No building shall be used for stabling cows for dairy purposes which is not properly constructed, well lighted, well ventilated, and provided with a suitable solid floor of plank, cement, or other impervious material that can be readily cleaned, and laid with proper grades and channels to carry off all drainage. (2) No water-closet, privy, cesspool, urinal, inhabited room, or work shop shall be located within any building or room for stabling cows, or for the storage of milk or milk products; nor shall any fowl, hog, horse, sheep, goat or other animal be kept in any room used for milking or for storing milk or milk products. (3) All rooms and stables in which cows are milked shall be thoroughly clean and in good repair, and shall be painted or whitewashed once each year. (4) All manure shall be removed daily from the room or stable in which cows are milked, and shall not be stored where odors from the same will be noticeable at the stable or milk room. (5) All persons keeping cows for the production of milk for sale shall cause each cow to be kept clean and groomed. (6) Each person using any premise for keeping cows shall cause the yard or pasture in connection therewith to be provided with a proper receptacle for drinking for such cows, and none but fresh, clean, pure water shall be stored in such receptacle. (7) Any inclosure in which cows are kept shall be graded and drained so as to keep the surface reasonably dry and to prevent the accumulation of water therein, and no garbage, urine, fecal matter, or similar substances shall be placed or allowed to remain in such inclosure, and no open drain shall be allowed to run through it. (8) All milk shall be removed, as soon as drawn, from the stable to the milk room. The milk room shall be separate from the stable in which the cows are kept, and shall not be used as a living or sleeping room, but shall serve for the handling and keeping of milk and cream exclusively. It shall be sanitary in construction, properly screened, supplied with proper ventilation, light, and pure water, and suitable facilities for straining, cooling, and storing milk or milk products, and for washing and sterilizing all utensils and apparatus in which milk is removed, stored, and delivered. (9) All utensils used for the reception, storage, or delivering of milk or cream shall be made of glass, stoneware, glazed metal, or tinplate free from rust and of sanitary construction. (10) All cans, pails, strainers, coolers, dippers, separators, bottles, churns, butter workers, and other dairy utensils shall be cleansed from all remnants of milk and scalded with boiling water or live steam after each use." (From Gardner and Simond's *Practical Sanitation.*)

9. *Acceptable methods for hospital ventilation* are: (1) *Natural ventilation*, which is best accomplished by having the wards built with windows on two sides (opposite to each other); these windows should be made to open at the top, they should extend from three feet from the floor to six inches from the ceiling. Ventilators in the ceiling are helpful. (2) *Artificial ventilation*, which requires special apparatus and special attention and care; the air has to be drawn in and pumped out; it should be warmed before it is admitted to the wards; it is liable to get out of order, and requires constant supervision. The incoming air may need to be filtered, or cooled, or washed. The problem of ventilation of hospitals is by no means settled; both methods have their faults and their advocates.

10. *The required cubic air space for hospital wards for children* is about 1000 cubic feet; *for infants*, about 1000 cubic feet; *for adults*, from 3000 to 4000 cubic feet.

PRACTICE, PATHOLOGY, AND DIAGNOSIS.

1. (a) *The physical signs* are very similar to those of a pleurisy with effusion; there will be absence of tactile fremitus, with dullness or flatness on percussion; local pain and tenderness; the breath sounds are distant, and are bronchial in character. Posteriorly there will be clear pulmonary resonance and normal respiratory murmur unless the primary pneumonia has in-

volved the lower lobe. The heart is pushed over to the right side; the right border is displaced outwards, and the apex is displaced inwards. Traube's semilunar space is probably clear. There will probably be a pericardial rub or a pleuro-pericardial rub. There will be a leucocytosis, and the whispered voice will not be transmitted (over the area containing pus).

(b) The *usual history* is that the condition follows a pneumonia, with an insidious onset; the temperature either does not fall or it rises again; there are symptoms of sepsis, malaise, chills, sweats, and a purulent fluid may be obtained on aspiration. The intercostal spaces may bulge. An *x*-ray should be taken to aid in the diagnosis, and care must be taken not to confound the condition with pericardial effusion or cardiac dilatation.

(c) The *differential diagnosis* is between the pneumonia, pleurisy with effusion, pericardial effusion, cardiac dilatation, and the empyema. The pneumonia will not give the displacement of the heart, the leucocytosis, or show pus on aspiration; the classic signs (such as the crepitant rale, etc.) will be present. The pleurisy with effusion will not give rise of temperature, evidences of pus, and aspiration will procure serous fluid. The cardiac conditions will show negative pulmonary signs. The *treatment* is by aspiration and drainage, or by resection of parts of one or more ribs, with drainage.

(d) *Thoractomy* should be undertaken about a week or ten days after the pneumonia has resolved (presumably), so as to allow for the formation of antibodies. But it may be necessary to operate earlier.

3. *The abdominal signs and symptoms in spondylitis* are: Pain and tenderness in pit of stomach, with a feeling of constriction; "bilateral belly-ache"; hyperesthesia, with weakness and atrophy of the abdominal muscles.

4.

ASCITES.	OVARIAN CYST.
1. Previous history of visceral disease.	1. No such history.
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovariana. Anemia absent, or later.
4. Patient on back, enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change.
6. Navel prominent and thinned.	6. Navel usually unchanged.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity, and dullness in lowest parts for all positions—*i.e.* areas of resonance and dullness change with position.	8. No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency; albuminous, but does not coagulate spontaneously; may contain colloid matter.

—(From Dudley's *Gynecology.*)

5. Assuming that the lesion is a *chancre*, it should be kept clean, protected, covered with a small amount of a 33 per cent. calomel ointment applied twice a day for about a week, and protective gauze. Excision or cauterization is not recommended.

6. *Excess of fat in the diet* produces gastro-intestinal disturbances, vomiting, and diarrhea.

Excess of carbohydrate in the diet produces an appearance of plumpness, but the muscles are flabby, the skin is pale, and the bones are inclined to be rickety; griping and diarrhea may be present.

8. *Petechiæ* are small spots in the skin, due to effusion of blood.

Pyuria is the condition in which the patient voids urine containing pus.

Choked disc is a papillitis with serous infiltration; it can be recognized only by the ophthalmoscope.

Babinski's sign is a lessened or absent Achilles tendon reflex in sciatica which is not hysterical; also, extension of the toes (instead of flexion) on tickling the sole of the foot.

9 and 10. With such a very unsatisfactory history no competent person would venture on a diagnosis. Among the possibilities are hyperthyroidism, lead poisoning, hysteria. Before a diagnosis is even thought of a proper history should be presented.

(*To be concluded.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

FEEBLENESS OF GROWTH AND CONGENITAL DWARFISM. By DR. MURK JANSEN. 82 pages with illustrations. Published by Henry Frowde and Hodder & Stoughton, London.

Miscellany.

A GLIMPSE OF CHINESE MEDICINE OF THE MIDDLE AGES.

By M. FORD MORRIS, Jr., M.D.,

ATLANTA, GA.

JUNIOR VISITING PHYSICIAN TO THE GEORGIA BAPTIST HOSPITAL; VISITING PHYSICIAN TO THE ANTI-TUBERCULOSIS ASSOCIATION; INSTRUCTOR IN MEDICINE IN THE SCHOOL OF MEDICINE OF EMORY UNIVERSITY.

But wherefore seek immortal life by means of wondrous pills?
Noise it not in the market-place, nor quiet on the hills.
The secret of perpetual youth is already known to me:
Accept with philosophic calm whatever fate may be.
—MA-TZU-JAN.

ALTHOUGH the Chinese were shut in for centuries by the never-ending walls which mark the boundaries of this Mongolian kingdom, and so had nothing of our Western civilization, they had a high degree of civilization of their own, and led the West in many directions. Their leadership was not confined to any particular line of endeavor. As we are especially interested in their practice of medicine, we shall confine our researches to that subject. In reviewing the Chinese literature from B. C. 2357 to A. D. 1848, we find several incidents of interest. About A. D. 1200, a judge named Sung Tz'u published a curious book on Medical Jurisprudence which is still much in use. After twenty-six years of unremitting labor, Li Shih-Chen completed, in 1578, his great Materia Medica. More interesting than these, however, is one Dr. Hua.

This famous Chinaman will be remembered for the reason that he was doing major surgery under anesthesia long before painless operations had been dreamed of in other lands. This is, indeed, a remarkable fact, occurring as it did in the latter part of the thirteenth century. In the account of this wonderful man are related facts which some of us supposed were of comparatively recent discovery. But for a sad experience which an emperor had with Hua, the doings of this Mongolian physician might never have been set down.

Being a great general, Ts'ao Ts'ao became in time an emperor. One day he attempted to cut down a pear tree. The spirit of the pear tree struck him so violently on the head with a sword that the resulting wound was a source of much agony. One of the minor officers recommended a certain skillful physician. This man told his ruler that Hua's administration of drugs and his use of acupuncture and counter-irritants were always followed by a speedy recovery of the patient; that, if the sick man was suffering from some internal trouble, of which medicines produced no relief, then Dr. Hua would administer a dose of hashish, under the influence of which the patient would become intoxicated as by wine. "Then," continued the advisor, "he takes a sharp knife and opens the abdomen, washes the patient's viscera with medicinal liquid, sews up the wound with medicated thread, and puts over the incision a plaster—all without the slightest pain; and by the end of a month or twenty days the place heals up."

The narrator then relates several incidents to show Dr. Hua's extraordinary skill. If the reader is skeptical regarding the following facts, he may verify the translation from the original Chinese:

One day, for instance, as he was walking along a road, he heard someone groaning deeply, and at once declared that the cause was indigestion. On inquiry, this turned out to be the case; and accordingly Dr. Hua ordered the sufferer to drink three pints of a decoction of garlic and leeks, which he did, and vomited forth a snake between two and three feet in length, after which he could digest food as before. On another occasion, the Governor of Kuang-Ling was very much depressed in his mind, besides being troubled with a flushing of the face and a total loss of appetite. He consulted Dr. Hua, and the effect of some medicine administered by him was to cause the invalid to throw up a quantity of red-headed wriggling tadpoles, which the doctor told him had been generated in his system by too great indulgence in fish and which, although temporarily expelled, would reappear after an interval of three years when nothing could save him. And sure enough, he died three years afterwards. In a further instance, a man had a tumor growing between his eyebrows, the itching of which was insupportable. When Dr. Hua saw it, he said, "There is a bird inside," at which everybody laughed. However, he took a knife and opened the tumor and out flew a canary, the patient beginning to recover from that hour. Again, another man had his toes bitten by a mad dog, the consequences being that two lumps of flesh grew up from the wound, one of which was very painful while the other itched unbearably. "There are ten needles," said Dr. Hua, "in one sore lump, and two black and white weichi pips in the other." No one believed this until Dr. Hua opened them with a knife and showed that it was so.

At this point of the narration Ts'ao Ts'ao sent away messengers who traveled night and day and brought Dr. Hua before him. The emperor held out his wrist and asked the physician to take his pulse and diagnose his case.

"The pain in Your Highness' head," said this Chinese man of medicine, "arises from a wind, and the seat of the disease is the brain, where the wind is collected, unable to get out. Drugs are of no avail in your present condition, for which there is but one remedy. You must first swallow a dose of hashish and then, with a sharp axe, I will split open the back of your head and let the wind out. Thus the disease will be exterminated."

Ts'ao Ts'ao flew into a great rage and declared that it was a plot aimed at his life. To which the Oriental surgeon replied: "Has not Your Highness heard of Kuan Yu's wound in the right shoulder? I scraped the bone and removed the poison from him without a single fear on his part. Your Highness' disease is but a trifling affair; why, then, so much suspicion?"

The emperor did not consider the disease or the cure the least bit trifling. And being enraged at that which he thought was an attempt to kill him, he ordered the doctor to be seized and cast into prison, where the unfortunate and innocent man soon died. Before very long, too, Ts'ao Ts'ao himself succumbed.

Both died, when each might have saved the other. A tragic and untimely end was Dr. Hua's. No stone marks the final resting place of the body of such a man. His grave may be high up in the mountains, where the only friends of his earthly house are frozen ground and snow, with the cutting wind overhead wailing its mournful requiem. His bones may lie in some sunny river

valley where the sad twilight lullabys of the blowing fields of rice and the heavy odor of countless water lilies are the lone companions of that eternal night.

CANTLIE BUILDING.

SOME CHANGES.

WHO recalls the Society Meetings at the Old Academy of Medicine of the New York County Medical Association? Do you remember those days in 1892-93-94, etc.? I am referring to the days when McLeod was President and P. Brynberg Porter was Secretary; to the days when Sayre, the great father of orthopedics, attended the meetings and discussed our papers vigorously, but when the scientific order of business was over he then entered into the convivial section of the meeting very earnestly and enchanted his associate fellows with his ever jovial and entertaining personality. Yes! those were the days when George Tucker Harrison, while in scientific session, told us how to handle a prolapsed cord, but during the social period how the Yankees freed the horses in the South. Yes! To the days when singing was still permitted, and many was the time when an impromptu "Glee Club" rendered selections which would never pass modern censorship.

You know I am referring to the days when all the Fellows were good fellows, whether the leaders in the profession of their day or the young man just starting a career. A fraternity existed, a professional and social unorganized association of gentlemen, basing their code of ethics, not upon any legislative enactment, but upon the teachings they received while sitting on their mothers' knees.

I ask, why have these medicosocial societies gone? Some of my intimate friends tell me they think it's prohibition. Then, I ask, why should prohibition have such an effect? I am told without a moderate amount of stimulation the best in man may remain dormant. And then they attempt to prove this assertion by calling to mind Shakespeare, Shelly, Burns, Keating, Scott, Longfellow, Dickens, Henry Clay, Daniel Webster and some others whose names I have forgotten, with the exception of our great American, Teddy Roosevelt.

When I observe things as they were, and as they are, I fail to see where, in the law of average and equity, there has been anything gained thus far.

E. STYLES POTTER, M.D.

150 WEST FORTY-SEVENTH STREET,
NEW YORK.

The Bubonic Plague in Paris in 1920.—The existence of the plague in Paris during 1920, which was at first carefully concealed, is now freely admitted; and the medical press has published several accounts of it. One of these by Rathery appeared in the *Journal de médecine et de chirurgie pratiques* early in the year. The first case was reported secretly to the Société médicale des hôpitaux on June 25, 1920. Cultures of the bacillus of Yersin had been obtained from the body of an infant dead of some obscure malady Mlle. Pfeffel, who was one of the bacteriologists, was also quite certain that she had obtained a similar find in another child dead in December, 1917; so that if she was right the disease may have lurked in Paris for three years. Nor was this the only old case. But in such isolated episodes the bacteriologists were not entirely sure of their diagnoses, and it is, moreover, certain that epidemics did not follow, although apparently no preventive measures were then inaugurated.

No new case came to light until August 3, 1920, when a patient entered the Tenon Hospital in Rathery's service. This woman, aged 24, was accompanied by a sick baby and both were found to have severe septic phenomena with some cervical adenopathy. But the gastroenteric tract bore the brunt of the symptoms, there being profuse fetid diarrhea with vomiting. The infant died and hemoculture showed only the pneumococcus. In the meantime the husband of the woman became severely ill and presented inguinal adenopathy, while three other members of the family died soon after, having been stricken with the same disease. The husband having succumbed, his blood was found to contain the *B. pestis*. The blood of the wife contained both the *B. pestis* and the pneumococcus. Without further details, the author states that the entire number attacked by the plague to the date of the report was 18, with 8 deaths; this refers to the one group of cases, without reference to earlier isolated examples of infection.

In addition to this group, other scattered foci have since appeared. The number of cases per focus has been 4, 6, 10, and upward. These foci, while scattered widely, show some tendency to concentration in certain quarters. Each focus was stamped out by the usual measures, and in a short time the city was free, while it became a simple matter to trace the contagion backward.

The number of symptoms was bewildering, and, in addition to the classical ones, others are mentioned as of common occurrence. Purpura and various rashes are enumerated, with mastitis and parotitis. The conditions most closely simulated were typhoid fever and ordinary sepsis. Pneumonia is hardly mentioned. Of great interest was the occurrence of walking cases for the author believes that an ambulatory abortive form is common. There may be adenopathy, with a little fever or none at all. These people went about their business as usual, but some of them went to surgical clinics for acute suppurating glands. In general, one should be a little suspicious of such cases until they are proved innocent. Any unusually large mass of inflamed glands in the neck, armpits, or groins should be watched unless there is a sufficient cause in evidence. Serotherapy gave results in the writer's cases equal and perhaps superior to those in diphtheria.

Outcome of a Case of "Rejuvenation."—Professor Sauerbruch was consulted by an elderly man for a felon. This patient turned out to be one of the men "rejuvenated" by the Steinach-Leichtenstern operation. Before the intervention he had been sexually weak from the age of thirty-four and unable to copulate save with certain women. After the operation his potency improved but was still relative; he still had to find the special type of woman.—*Wiener klinische Wochenschrift.*

TREATMENT OF SOME FRACTURES OF THE LONG BONES, INCLUDING SOME FRACTURES OF THE PELVIS.

BY ETHAN H. SMITH, M.D.,

SAN FRANCISCO.

FIRST of all let us discuss some of the modern ideas as to the treatment of fractures. We hear much at the present day of the standardization of splints. It would seem that an effort is being made to make the treatment of fractures conform to the same mechanical rules applicable to the machine shop or wood working factory where materials are turned into newly manufactured articles, where it is possible to turn out parts by piece work according to standard patterns. New parts to repair broken ones can be made from the same patterns with great mechanical accuracy. These can be supplied by the trade throughout the entire world.

Until we can standardize human beings as to size, weight, shape, including length, breadth, and thickness; and eliminate possible complications in the way of under-development during childhood, and conditions caused by existing disease, malnutrition, old age, and many other circumstances incident to human existence at the present day, it must be readily seen how well nigh impossible it is to think of standardizing splints or anything else of a mechanical sort necessary to the treatment of fractures or deformities. Our work is repair work. We are dealing with damaged human beings, many of whom are ill formed or unsound, undeveloped or damaged by age. We cannot take the human machine all to pieces on a bench or floor and throw out positively used-up pieces and reapply new material, as can be done with inanimate materials in the shop.

We are going through a period of readjustment from the great world war. In the field and base hospitals with tens of thousands of wounded, requiring immediate care, measures had to be adopted looking to the conservation of life first of all, and the giving of immediate aid to as many wounded as possible in the limited time at hand and under such circumstances as were forced upon the surgeons through no fault of their own, but through force of circumstances ever existant in the world.

In the reconstruction hospital the great problem confronted the surgeons of salvaging from the vast amount of human wreckage, as much as possible and restoring to the unfortunate wounded as much as surgical skill could give them.

Our surgeons of the various countries involved, found it necessary to go back and review the literature on fractures and from some of the men of long ago, adopt ideas as a basis, and then, by applying modern ideas, establish a routine for the handling of fractures. Much of that routine must be abandoned, and a wide latitude given to the surgeons with greatest skill and most originality in bringing order out of the chaos of the war period. It is not going to be done by a standardization of splints. Much of our present day literature is based on the practice of surgery as it exists in large, well equipped hospitals. I have no desire to criticize the excellent work that is being done in many large hospitals in many countries. However, in a consideration of the care of fractures, we must consider the circumstances under which the general practitioner is obliged to work, in districts remote from well equipped hospitals. A goodly proportion of fractures occur in communities and under circumstances making it impossible for the patient to be cared for under ideal conditions. My own attempts to instruct are made largely in behalf of the men who must care for fractures in private homes, logging camps, and ill furnished charitable or semicharitable institutions.

We do not give sufficient consideration to the lack of manual skill on the part of those who are going to treat fractures. Students going through a medical school and after graduating, serving as interns cannot have the necessary training to make them expert in the application of the many appliances necessary for the successful treatment of fractures. Many of these students have never followed a vocation in which their hands became skilled in the manipulation of mechanical contrivances. We unload an avalanche of technical and scientific mental training on our medical students. They do not and can not have much training calculated to develop manual skill in the handling of fractures. However, this latter condition can be remedied quite materially if our instructors in surgery put themselves to the task of solving the problem.

I wish to say a few words concerning the use of plaster of Paris. Much of the plaster of Paris work of the present day is unpardonably bad. Ninety-nine out of a hundred of all pressure sores are preventable. The use of plaster of Paris has not been given careful and studious attention by the bulk of those who have been employing it. It is taken as a matter of course and the plaster is slapped on with little regard for consequences. In our endeavor to secure accurate adjustment of fractured bones, we have been led into the error of putting them up too tightly. The use of sheet wadding has become universal through habit and because it is cheap. It was never a fit material to use for splints or underneath plaster of Paris. It does not sufficiently pad

over bony prominences, mats down, wrinkles, retains moisture from perspiration, and soon becomes offensive. If there are any abrasions or wounds which may exude moisture this is retained in the damaged area and forms a very favorable culture for the development of infecting organisms. I realize from the positive assertion that I have made that I am going to arouse the antagonism and possibly the ire of some of my fellows in the profession. While I do not wish to appear unmindful of the good will of my fellows I am willing, for the sake of the patients who suffer, to be responsible without apology for the statements I have made.

Sized crinolin which is made stiff by glucose sizing is unfit for use in plaster of Paris bandages. The sizing has a deteriorating effect on the plaster, causing it to remain soggy for hours or days after it is applied. Frequently it has been found that a plaster of Paris dressing has been warped or bent after the manner of a lead pipe and a fracture which was in good position at the time of the application of the dressing will have become displaced, or partially so, from the change in the contour of the plaster. Modeling compound, commercial plaster, and flasking plaster are unfit for use in surgery. Dental impression plaster, thoroughly dry and undamaged by moisture, is the only fit plaster to use. Unsized gauze of not too fine a mesh makes an ideal bandage.

Best quality of absorbent cotton in pound rolls so as to have a good width of material carefully cut into shape by sharp scissors and smoothly applied to the part, with strips of cotton to reinforce exposed or bony prominences and bound into place by very coarse meshed gauze bandages gives the very best material which we now have, over which to apply plaster of Paris. The normal contour of the part to be covered by plaster should be approximated by the careful application of the bandage outside of the cotton. Plaster of Paris is obtainable in any community at the present time. The bandages should be freshly made from unsized gauze and good impression plaster by the surgeon or assistant, and none of the abominable commercial canned bandages should ever be used for any purpose. Do not immerse the bandages in salt water, because the impression plaster sets so quickly that it needs nothing to hasten it. Bandages should not be more than five yards in length (if the surgeon is a slow worker, three yards is better). Salt makes the dressing as brittle as glass. Cold water is uncomfortable to everybody concerned and has nothing to recommend it. If the bandages are loosely rolled and slowly dropped endwise into the water they will settle on end in the bucket and rapidly soak through. The assistant handling the bandages should keep the hands dry at all times. To have an assistant grasp a bandage by both ends, plunge it into a basin of water and imitate the playing of an accordion, thus washing all the plaster out of the bandage and then hand the wet rag to the surgeon to apply, is a sarcasm on the art of using plaster of Paris in surgery. A bucket with water deep enough to submerge any bandage set on end, should be provided.

After the Civil War, had the surgeons who had served through that period presumed to demand a standardization of splints (and they used many splints those days, as plaster of Paris had not been discovered as a dressing for fractures), we should still be doing fracture work according to the Civil War Period. Who is going to standardize splints? Who is going to presume to approve of them? Where are the specifications for their proper manufacture? Where are the shops in which they may be made? Who has any idea that they would be uniform in specification or construction, if we should all agree to use them? Standardization of hospital technique may be accomplished, and is right, providing it is occasionally revised. Standardization of splints and appliances must ever yield to progress. Some mechanical principles have been evolved in the past, that are as good today as when they were discovered, but many appliances are in the rubbish heap.

I shall now take up the treatment of the fractures of the long bones and also of the pelvis. I shall take up the pelvis first out of its order.

Fractures of the pelvis were formerly very rare. Automobile accidents have made them frequent. Before the advent of the *x*-ray many of them were never discovered. At the present time many obscure fractures of the pelvis are not diagnosed because they are not suspected and radiograms are not made.

For convenience of discussing treatment of fracture of the pelvis, these fractures may be divided into three general groups. Group I. Those fractures involving the acetabulum in which the acetabulum is driven into the pelvic cavity. Group II. Those involving the inominate bone without depressing the acetabulum and with expansive separation of the fragments. Group III. Those fractures in which neither separation of the fragments nor deformity occurs. In group I, in which there is depression of the acetabulum with the head and neck of the femur following deeply into the pelvis it is obvious that plaster of Paris should never be used. This will fix the deformity and cause malunion and permanent crippling. Tight strapping around the pelvis is equally bad. By making traction on the lower extremity, the capsular ligament of the hip joint will usually pull the broken fragments nicely into place and maintain them there. Failing in this, replacement and suture will be necessary. Recovery may be so complete as to leave no visible trace from the outside. In those fractures in which there is expansive separation of the fragments, the condition is reversed and firm strapping about the pelvis is indicated. Plaster of Paris is not indicated as it increases the pain and discomfort of the patient and the fractured parts cannot be held in close enough apposition to keep them in place while the plaster is being applied. The strapping is much more simple and answers every purpose. Group III requires merely rest in bed.

Fractures of the Long Bones.—Fractures of the humerus, because of the peculiarly exposed position of the arm, whether at rest or in action, are more apt to be transverse or only slightly oblique when occurring in the middle or lower portion of the shaft, than fractures in any other of the long bones. The medullary canal is relatively small in this bone. The bone itself is more compact than any other of the long bones. Unless reduction of the fracture is

more accurate than in fracture of other long bones and the separated portions of the medullary canal are more certainly opposed, delayed union or non-union is more liable to occur than in any bone in the human body. Some of the splints developed during the war period for treating fracture of the humerus are excellent. It seems stronge now that we had not thought of them more generally before. They accomplish just what should be sought after in the treatment of the fracture of any bone. They produce a maximum of muscular relaxation thus permitting the fragments to drop into place without using undue force, where they may be easily kept in position. This plan of treatment has been unfortunately reversed by most surgeons in handling fractures of the lower extremity. I will speak of that later. In necessary operations on the shaft of the humerus, the musculospiral nerve should be located as soon as the incision is made, when necessary to operate in the vicinity of that nerve. It should be gently and carefully pulled out of harm's way by a soft gauze strip and the utmost care used not to meddle with it more than can be avoided. It should not be handled with metal retractors. As a rule the step-cut splice can be more readily done, when necessary to repair the bone in case of non-union, than the application of a bone transplant. However, if the bone in either fragment is ecchymotic or has the appearance of not being fully vital, an inlay transplant should be done, which transplant should be long enough to reach from thoroughly vital looking bone in one fragment over into equally good bone in the other fragment. The ends of the bones should be carefully cleared of all soft callus or fibrous structure. It is not best to saw off the bone transversely. A transverse cut in bone is very frequently soon covered over by fibrous tissue, which may prevent union for the second time. Leave the rough surface, thoroughly clear out the medullary canal so as to make way for restoration of the nutritive circulation through the bone. Leave all metal bands, plates, staples, and similar obsolete junk absolutely out of the arm.

Fractures of the shaft of the radius or ulna will usually unite very readily if once well reduced. Because of the peculiar function of the forearm and the tendency for many fractures of these bones to be nearly transverse when occurring in the shaft, reduction is often difficult. The appearance of the forearm from the outside is very deceptive. It is no kindness to the patient to give an anesthetic and wring and twist and pull at the parts in a vain endeavor to reduce over-riding transverse fractures. Make a moderate incision and with the bone skid gently, but postively reduce the fracture. If the fracture is fully reduced it requires no fastening to remain in position in the vast majority of cases. If it must be secured, do so with kangaroo tendon and do not use any sort of hardware. The kangaroo tendon can be introduced with great facility by means of untempered steel bone needles. These can be bent to any desired curvature during the operation.

Most Colles' fractures can be, and should be reduced without an anesthetic. Ten anesthetics are administered in the handling of fractures where one is really indicated. I regard this as a conservative statement. With children, terror of the doctor and his preparations for work is the factor which frequently compels the use of an anesthetic, rather than any pain incidental to work when skilfully done. Gentle handling will reduce well nigh any Colles' fracture without the necessity of an anesthetic. Anesthetics have led to the most inexcuseable and unnecessary rough handling of fractures. Much of the disability following simple fractures is due to reckless disregard of the integrity of the soft parts during the manipulation incidental to putting up a fracture in some sort of dressing. I am well aware that a proper dressing for Colles' fracture is a subject for great combat of opinion. After many years in handling many of these fractures and observing the handling of them by many other surgeons I am convinced that nothing affords such uniformly good results as a properly applied plaster of Paris dressing. (The placing of the hand in marked dorsiflexion is to my mind grotesque to say the least; I shall waste no more words on it.) The hand should be slightly flexed anteriorly; slightly flexed on the ulna; the forearm flexed to a right angle with the arm, with the hand midway between pronation and supination and then smoothly enveloped in first class absorbent cotton, carefully cut in shape, from a pound roll so as to have the necessary width, and the cotton bound firmly but not tightly into place by a very soft loose mesh gauze bandage. Plaster of Paris should then be put on from the fingers to the axilla, and reinforced at the elbow by a couple of small strips of yucca stem to prevent breaking. The plaster should be trimmed out so as to give free use of the fingers and thumb and the dressing immediately split up the dorsum of the hand, forearm and outer side of the arm. Patients should be encouraged to move the fingers and thumb freely and frequently. This dressing left in place for four weeks, without any foolish meddling with the wrist while there is possibility of motion between the broken fragments gives universally good results. Any splint is objectionable, because it makes clamp like pressure on the parts, both front and back, and is one source of serious adhesions. I am prepared to have this treatment combated, but I am also certain that many of my fellows in the profession will come to see that it is good treatment.

A transverse fracture of either the radius or the ulna, or both bones, at a distance of one or more inches above the wrist joint, produces a condition that is wellnigh impossible to handle safely or properly without incision and reduction of the fragment with the aid of a bone skid. It is not often necessary to suture the fragments after reduction. If suture is necessary, kangaroo tendon used with the untempered steel bone needle gives most satisfactory results. All metal contrivances should be obsolete at this time; just as much so as the Murphy button in the suture of intestines. Plaster of Paris from the fingers to the shoulder with the forearm at a right angle to the arm, with the radius and ulna midway between pronation and supination gives an ideal dressing. It is preposterous to put any sort of dressing on a fracture of the forearm which permits pronation and supination. No dressing that does not include the arm will prevent that function.

All fractures of the femur can be better handled and much more comfortably and safely handled

without the use of plaster of Paris than with it, except in some operative cases. The use of the Hawley table should be mentioned only to condemn it, as a retrograde in the surgery of fractures of at least a century. It substitutes brute force and awkwardness for skill and intelligence in the treatment of fractures of the lower extremity.

In fractures of the neck of the femur whenever the lower extremity is abducted, the adductor muscles serve as a fulcrum while the upper extremity of the femur adjoining the neck serves as the short arm of the lever, while the whole thigh and leg serve as the long arm. The adductor muscles pull not only inward, but upward. The fragments involved in the fracture are unnecessarily jammed and over-riding of the neck of the femur by the shaft is almost sure to follow. Shortening of an inch or more is the rule, rather than the exception. It does not matter who the surgeon is, or whether he uses a Hawley table or not, the above mentioned holds good.

If we use a straight pull with the old time weight and pulley, we shall bring the limb down to the normal length. When the leg and thigh rotate outward, as they do invariably in this fracture, the fractured parts are not separated in a parallel manner, but open up like a book. By strongly rotating the thigh and leg inward, at the same time lifting forward on the great trochanter, the fracture may be brought into perfect apposition. A small sand bag, about two-thirds the size of a brick and not tightly stuffed, with a pad on top of it should be placed behind the trochanter, then with big sand bags, one reaching from the level of the tenth rib to the bottom of the foot on the outer side, and the other from a few inches below the perineum to the bottom of the heel on the inner side, tied into place by strips of bandage, two below the knee and two above with a long thin pillow used as a pad to protect the bony prominences, and placed underneath the leg and thigh and brought up on the sides, so as to intervene between the sand bag and the limb. The upper end of the sand bag should be bound in place by an abdominal binder. The sand bag should be big enough to prevent the strips of bandage from cutting into the thigh or knee. A good quality of moleskin adhesive plaster should be used to make traction. Spiral strips should be discarded, the foot should be bandaged with a flannelette bandage and the leg and thigh also with the same material. The patient's body can be raised and lowered, as moderate movement of the hip joint will not displace the fragments in a fracture dressed in this manner. It is vastly more comfortable than any plaster dressing could possibly be. It requires absolutely no anesthetic in any patient of any age. It can be applied by one doctor without any assistant if necessary. Pneumonia is practically unheard of. Recovery with shortening scarcely to be demonstrated is the rule. Rotary displacement is avoided. Function of the hip joint will be from 50 to 70 per cent. of the normal which is as good or better than when other methods are used.

Fractures of the shaft of the femur may be treated by the same method with excellent success when they can be readily reduced. Transverse fractures of the femur are the ones that are difficult of reduction.

Oblique fractures of the femur slide readily into place if permitted to do so with gentle handling. Rough handling, either with or without an anesthetic, means more traumatism, more hemorrhage, more muscular edema, and much more muscular spasm. If a transverse fracture cannot be readily reduced without great force, cut down upon it and reduce it with a bone skid. Paralysis of the bladder has been produced by the use of the Hawley table in reducing difficult transverse fractures of the femur. Many muscular fibrillæ are destroyed by the same means, leaving permanently impaired muscles. In compound fractures of the femur, or multiple, or badly comminuted fractures of the femur, nothing equals a modified Hodgen splint. The Thomas splint was an admirable affair for transporting patients in an ambulance to where they could have better care. The clumsy makeshift affairs that are turned out in most parts of the world and called Thomas splints are positively bad and could not give good results. Pressure sores are common in the ischial region, the muscles are not relaxed as they can be by the use of the modified Hodgen splint, and the patients are much less comfortable.

Very few fractures of the femur require operative repair. Metal plates produce more rapid destruction in the femur than in any other bone and frequently defeat the purpose for which they are used. Metal bands surrounding the bone are ungainly and unnecessary foreign bodies. A kangaroo thong wound around an oblique fracture holds it as securely, or more so, than a metal band and disappears when its function has passed.

Inlay bone transplants are permissible in the femur, a medullary transplant never. It plugs the medullary canal and prevents the restoration of the nutrient circulation through the bone. Sometimes it prevents the repair of the bone, each end of the peg uniting within the medullary canal of each fragment, with little or no union between the fragments. In such cases the peg promptly snaps off and produces a very mean operative case with the prospect of a great deal of trouble before recovery is complete.

Nearly all fractures of the leg can be easily and readily reduced in the recent state, if the knee is semiflexed, and held in that position during the necessary manipulation incident to the reduction of the fracture. Trying to reduce a fracture of the leg with the knee in complete extension is about as sensible as trying to drive away with a horse, without untying him from the post. After the fracture is reduced, a plaster dressing extending from the toes to the gluteal fold between the hip and the thigh and fixing the knee in semiflexion should be applied. A properly shaped pad of absorbent cotton accurately cut from a pound roll, should be placed next to the skin and firmly but not tightly bound in place by very coarse meshed gauze bandage. This is the dressing suitable for closed fractures including Pott's fractures. There is this exception, in the typical Pott's fracture the foot should be inverted and always without exception brought to a right angle or more with the leg. If the fracture is through the external malleolus at about the level of the ankle joint, the foot must not be inverted or everted, but put up in the straight

position with the foot at a right angle to the leg. In compound fractures of the leg, requiring dressing for some time or frequent inspection, the plaster may be reinforced with three-fourths inch strips of galvanized iron on the side opposite the wound. (Tin is useless.) Then a sufficiently large fenestra may be cut out so as to afford ample room for dressings and also the removal of all soiled gauze, leaving nothing to become offensive in the vicinity of the fracture. The trap cut out should always be replaced over dressings to prevent swelling and edema. The modified Hodgen splint is most excellent in compound fractures, multiple fractures, badly comminuted fractures, or V-shaped fractures with longitudinal splitting of the bone. The Hodgen splint can be made by any blacksmith of ordinary skill, and is well-nigh fool proof in the hands of the general practitioner, which is not the case with the Thomas splint.

Very few closed fractures of the leg when uncomplicated, ever require operating upon. Thousands of legs have been unnecessarily opened, many of them through a bad psychological frenzy, that sometimes afflicts the medical profession in surgery, to do what the other fellows are doing, but if possible do more of it. Lane plates and other metal devices have destroyed more legs than were ever necessarily saved, because of them. This statement holds good when we think of the thousands of legs that got well in spite of the so-called internal splint and which would have recovered more safely and just as well without operation.

In operating on a fracture of the leg, inlay bone transplants are permissible. A medullary bone transplant, never. It prevents the restoration of the medullary circulation through the bone and frequently gives rise to a throbbing pain at the site of fracture that will remain until the pressure from the medullary plug is relieved.

Never take a bone transplant from the crest of the tibia. The bone is too dense and does not readily unite in other locations to which it is transplanted. The medullary canal of the tibia is not opened up, and because of this fact, and the density of the bone in this location, little or no repair takes place in the tibia. It looks like a top board of a fence that the horses have been chewing. Worse yet, the tibia is very easily damaged and apt to be painful on slight provocation for all time to come. An inlay graft can be sawed out of the face of the tibia with less than half the trouble and within a few weeks the slot from which it was taken will have made a perfect repair. Do not make a sliding bone transplant from damaged bone and do not be content with applying a bone transplant wholly within partially devitalized bone. As well try to graft a half dead scion from one tree to a half dead limb of another, as to transplant partially devitalized bone into partially devitalized bone. Recently much has been said about sawing out the transplant, because of overheating the bone. The man who is not a good enough practical mechanic to run his saw without choking it and making it heat, should leave such work to surgeons with more skilful hands and better mechanical training.

Bone cut transversely and very smoothly is prone to fill rapidly with soft connective tissue which will so plug the bone as to prevent solid union. Bone cut obliquely or longitudinally tends to unite kindly, the bone structure is more freely opened up, leaving more spacious channels through which reparative tissue may reach the desired place. Do not place bone transplants in salt solution or meddle with them more than can be helped, during the process of the transplanting. Cut a neat and careful seat for the transplant and get it ready, then cut the transplant to fit, lift it out and place it in its new position and as speedily as possible fix it there.

A fracture of the neck of the femur very rarely requires operation. The use of a machine to turn a round bone peg to transplant into the neck of the femur is a ridiculous waste of time and endangers the integrity of the bone transplant and the freedom of the wound from infection. A quarter or three-eighths inch chisel graduated on one side in quarter inches may be used, first to cut a square hole out of the compact shell of the trochanter major and then lightly driven, occasionally loosening it, into the upper portion of the neck of the femur until it reaches the head. The distance from the greatest convexity of the trochanter major to the insertion of the ligamentum teres in the adult male subject is almost uniformly three and five-eighths inches. In the adult female, three and three-eighths inches. Knowing this, we may always see when we are at a safe depth, by seeing how deeply we have driven the chisel bit. The seat for this bone transplant should never be in the central portion of the femoral neck, as in that location we have a vast amount of fatty tissue making almost a medullary canal, rendering the bone transplant well-nigh useless and making a ghastly farce in the event of a nail or a wood screw or other metal abomination being used in this location. The bone transplant should traverse the upper portion of the femoral neck in order to get best results. The chisel when withdrawn from the hole in the femoral neck is then laid down on the face of the tibia and with a scalpel, a bone peg is marked out and quickly sawed to fit the hole in the femur. The medullary tissue and the periosteum should be removed before placing this peg within the femoral neck, otherwise there will be no union. It should be remembered that the periosteum limits the growth of the bone, forms a matrix on which bone may be reproduced, but has nothing to do with the reproduction of the bone. In the absence of infection osteogenesis takes place through the reparative material being conveyed to the part by the blood. In some cases, even in the midst of most serious infection, huge portions of new bone are produced. In such cases the periosteum is frequently largely destroyed before the bone is produced. The bone peg, as described above, can be very gently pushed or tapped into place. Valuable time and unnecessary meddling with the bone are saved and the surgeon is relieved of the necessity of buying a costly and unsafe machine. Smaller autogenous bone pegs can be very quickly and accurately shaved out with a sharp chisel by resting one end of the bone on a table while the other end is grasped by a pair of forceps. I shaved out one such peg and placed it through the two fragments of an ununited scaphoid bone of the wrist and secured a good result. If the ligamentum teres is ruptured and its accompanying artery destroyed, absorption of the head of the femur may occur.

Do not attempt a bone transplantation or any other operative repair as an immediate operation in compound fractures. Do not operate on such fractures, other than for the purpose of putting in drainage or cleaning out débris. Wait a week or ten days in closed fractures. It is safer, no matter who says otherwise. In compound fractures, wait until the original wound is healed and all signs of infection, either latent or active, have positively disappeared. Do not reverse the longitudinal axis of a bone transplant in removing it from one place and applying it in another. It reverses all of the nutrient channels in the bone and may be the cause of failure in an otherwise well performed operation. Never undertake reparative work in the event of the discovery of pus that might not have been apparent before making incision.

We have been for many years very prone to put up our fractures in too tight a dressing. It is one of the most dangerous mistakes that any individual can make in putting up a fracture.

Nothing is superior, in the treatment in most fractures of the clavicle, to the time honored dressing of the late Lewis A. Sayre. This dressing should always be put on with moleskin plaster, otherwise it is not a Sayre's dressing. A large pad which is unmentioned in many faulty descriptions of Dr. Sayre's dressing, should always be placed in the axilla, otherwise it is not a Sayre's dressing and is useless.

The writer does not expect everybody to agree with him. If he did it would be a waste of time to write this article.

Just a few words in conclusion about the use of electricity and also the idea of baking recuperating surgical parts.

In an occasional case a thoroughly well and safely constructed battery with accurate milliampere meter and everything strictly in good repair, electricity may be used by a fairly well trained electrotherapeutist with some degree of benefit. The haphazard way electricity is used by means of a lot of trashy batteries and by inexperienced, half taught, or wholly untaught individuals is a sarcasm on surgery. More muscles have been electrocuted in this way, ten times over, than have ever been benefited, even by the best of appliances.

A short time ago a very well trained young woman in reconstruction work in one of our largest and best equipped hospitals had been using the battery on a paralyzed lower extremity, which had been paralyzed because of damage to the origin of the sciatic nerve above the paralyzed part. She remarked that she could get no response whatever from the muscles by the use of the battery. The chief of staff to whom she had been speaking advised her to "turn on enough current so that you do get a response." Such advice was most ridiculous from a physical, a physiological, or a pathological standpoint. It is but an evidence of the truth that I have stated above.

About thirty-five years ago, at a time when bacteriology was in its beginning, somebody in the profession remembered the old story that used to be related in the old primitive works on Physics, of the two men who entered a huge oven with eggs and meat cooking all around them, were shut into the oven for a half hour or more and came out apparently unharmed. Immediately on its being found that heat was the best sterilizing agent, generally speaking, in the preparation for surgical procedures, someone thought that if we could only apply dry heat to a part or the whole of a human being, they could cook the infection right out of them. There was a great rage for baking appliances and a great deal of harm, and very little good accomplished. It led to more or less devitalization of the soft parts with permanent thickening of ligamentous joint structures which failed to function properly afterward, and so the joints never got well, and the muscles remained flabby for all time. The useless and dangerous lot of appliances met a quick and merited oblivion in most parts of the world. With the enormous amount of reconstruction work to be undertaken, following the world war, was opened up a great opportunity to make huge fortunes out of supplying batteries and bakers to be used in reconstruction work. The war psychology was propitious to the exploiting of the medical profession and the cripples both together. These abominable baking machines were resurrected, and have been supplied by the train load to all sorts and classes of hospitals as well as creeping back into private practice. Some day the baking machine will take its place along side of "tar water" and "tractors." The use of excessive heat causes the plugging of many lymph and blood channels by coagula and destroys the muscle fiber by half cooking it. In the part that is already attempting to undergo recuperation, this cannot do anything less than damage.

ACUTE SEPTIC PERITONITIS.

By JAMES A. MacLEOD, M.D., M.R.C.S., Eng., F.A.C.S.,

BUFFALO, N. Y.

ATTENDING SURGEON, BUFFALO CITY HOSPITAL; CONSULTING SURGEON, BUFFALO HOMEOPATHIC HOSPITAL.

"Acute septic peritonitis" is a disease which is always secondary to some acute lesion occurring elsewhere in the abdomen. Although it is most commonly due to some acute perforative lesion, such as a perforated gangrenous appendix, it may be due to a non-perforative lesion, such as an acute intestinal obstruction. In a recent contribution, entitled "Acute Intestinal Obstruction," I pointed out that, as the intestine above the site of the obstruction becomes paralyzed, bacteria pass freely through its wall and infect the peritoneum; a similar phenomenon occurs in any condition in which an intestinal paresis develops. Without going into the bacteriology of acute septic peritonitis, I may say that any of the pathogenic microorganisms may be the underlying factor in the production of the infection; in my practice, the colon bacillus has been the commonest offender. A few years ago, the late Norman K. MacLeod, in an investigation covering a large number of acute septic processes, recovered the organism of the infection from the blood and urine; and so one may say that in a large percentage of the cases of acute septic peritonitis we are dealing with, in addition to the local infection, a general septicemia. Whether the peritonitis is local or general depends upon the rapidity of the

disease leading up to the infection of the peritoneum. If the primary lesion be slow in its course, a protective barrier may be formed and the resulting peritonitis localized. If, however, the process leading up to the infection of the peritoneum be very acute, it is usually too rapid in its course to have a protective barrier built between it and the general peritoneal cavity, and a general peritonitis develops. In a general peritonitis we have a number of factors coming into play: The neuromuscular apparatus of the intestines becomes greatly stimulated, giving rise to increased peristalsis, which soon becomes reversed in character, as is made evident in the persistent and urgent vomiting. The vomiting in itself is extremely important, as it rapidly removes fluid from the general circulation and hurries the onset of an acute acidosis. The spasmodic peristalsis going on causes friction between the various inflamed peritoneal covered surfaces, and this causes great pain, which is the chief cause of the shock from which the patient is acutely suffering. As the disease progresses, the peristalsis lessens and the intestines pass into a paralytic condition; the vomiting continues, but it ceases to be urgent in character and becomes regurgitant, as is seen in intestinal paresis. Death takes place from a combination of toxemia, anaphylaxis, exhaustion, acidosis, and shock; and of these, the shock and acidosis are, in my opinion, the more important factors to be considered. If the shock and acidosis are combated successfully, the patient will generally take care of the toxemia and exhaustion, but occasionally the infection is so virulent and so widely spread that the patient is quickly overcome by the toxemia.

In making a diagnosis of an acute septic peritonitis, the causative factor, or factors, should be determined whenever possible. As a rule, the actual onset is difficult to place, as the disease is a continuation of the primary and causative lesion; the signs and symptoms becoming graver as they become graded into those of the peritonitis. In a well-developed peritonitis the signs and symptoms depend upon whether or not localization has become established. Where the disease has become localized the physical signs are more or less confined to that area. The condition may end in resolution or in abscess formation; where the latter occurs, a distinct tumor is to be made out. Where, however, the disease does not become localized, it progresses on to a general infection, the signs and symptoms of which may be briefly described as follows: The facial expression is one of great anxiety. The pulses are small, tense, and rapid. The temperature is elevated, although it becomes subnormal toward the end from toxemia; one of the most ominous signs to be encountered during the course of an acute septic peritonitis is a temperature falling to below the normal and an increasing pulse rate. Superficial tenderness and widely spread pain are prominent features throughout the course of the disease. The abdominal muscles are rigid and boardlike. Early in the case, urgent vomiting is a prominent sign, as the result of strong reversed peristalsis; as the case proceeds, the intestines become paralyzed and the vomiting becomes regurgitant in character, as is seen in other forms of intestinal paresis; it is never projectile, as is seen in cases of acute intestinal obstruction, unless the peritonitis becomes complicated by an intestinal obstruction. Distension is usually an early sign, and as the intestines become paralyzed it becomes very marked; it is associated with spasm of the abdominal muscles; in the most virulent cases, however, death may take place from an overwhelming toxemia before distention makes its appearance. In acute septic peritonitis, examination of the blood demonstrates that the leukocytes are increased in number and the polynuclear percentage raised, the percentage of the polynuclear cells being more important than the actual number of white cells; this also obtains in most of the primary lesions which are inflammatory in character. Examination of the urine demonstrates nephritic changes in direct proportion to the length and severity of the acute septic peritonitis; as already pointed out, the microorganism, the causative factor of the primary lesion and the acute septic peritonitis, may be recovered from the blood and urine. Constipation is an early symptom, and where the disease progresses on to intestinal paresis it becomes absolute; the passage of flatus during an acute septic peritonitis is a most encouraging sign.

In making a diagnosis of an acute septic peritonitis one has to consider other acute disturbances occurring within the abdomen, and of these the following are the most important: (*a*) Appendicitis; (*b*) Cholecystitis; (*c*) Gastrointestinal perforations; (*d*) Pelvic inflammations; (*e*) Ruptured extrauterine pregnancy; (*f*) Torsion of the pedicle of an ovarian cyst; (*g*) Acute pancreatitis; (*h*) Acute inflammation of an intestinal diverticulum; (*i*) Typhoid fever; (*j*) Mesenteric embolism and thrombosis; (*k*) Acute lead poisoning; (*l*) Acute renal infections; (*m*) Renal colic; (*n*) Biliary colic; (*o*) Acute intestinal obstruction; (*p*) Intestinal paresis.

The differential diagnosis between the above conditions and acute septic peritonitis, while it is in some instances somewhat academic in interest, is, however, of great importance, as it aids us in deciding whether or not an operation is necessary; and, where an operation is indicated, it gives us information as to the best possible situation in which to attack the existing disease.

Early in an attack of appendicitis the temperature and pulse rate are usually, but not necessarily, elevated. The right rectus muscle is in a state of spasm. Vomiting, if present, is not usually as persistent as in the case of peritonitis. There may be little or no distention. Later on, in cases which do not resolve or become operated upon, the signs and symptoms become those of the peritonitis which has developed.

In cholecystitis the physical signs are more marked in the upper right quadrant of the abdomen. The temperature and pulse rate are both elevated. The conjunctivæ and skin may be tinged with yellow; the urine and blood may show the presence of bile salts. Constipation is not marked, in fact a diarrhea may be present, as a result of a colitis, which is very often associated with cholecystitis. The stools, when present, may

be clay colored. Vomiting is not a marked feature of the case. Distention is not a prominent feature. The Murphy hammer stroke test elicits localized tenderness in the region of the gall bladder.

In a gastrointestinal perforation there is the history of the disease leading up to the perforation. Under this heading may be included those cases in which the peritoneum becomes infected, as a result of a perforative wound of the abdomen or an operation upon any of the hollow viscera of the abdomen. The actual onset is sudden and accompanied by marked signs of shock. The vomiting is not urgent. There may be evidence of free air in the abdominal cavity, with obliteration of part of the liver dullness.

In pelvic inflammations, the history, as a rule, will throw valuable light upon the subject. The temperature, pulse rate and leucocyte count are elevated. The physical signs are more marked in the lower abdomen. Vaginal examination reveals a tender mass in close relationship to the uterus, and fixing it. There may be an uterine discharge or a history of such. Vomiting is not a marked feature of the case. Constipation may or may not be present.

In ruptured extrauterine pregnancy the onset is sudden and accompanied by marked signs of shock and hemorrhage. If there is vomiting, it is not persistent. There is usually the history of a missed period, although such is not always the case. There may be a blood-stained uterine discharge as a result of the uterus casting off its false decidua; this commences immediately after the death of the fetus, and, when present, is practically diagnostic. There is a lowering of the hemoglobin percentage in direct proportion to the amount of the hemorrhage.

In torsion of the pedicle of an ovarian cyst there are marked signs of shock. The vomiting is not persistent. A movable tumor is to be made out in the lower abdomen; bimanual examination reveals the tumor as arising out of the pelvis.

In acute pancreatitis the onset is sudden and accompanied by signs of intense shock, very acute pain in the upper part of the abdomen, and vomiting. There is little or no distention in the early stages, although it does make its appearance later on. Vomiting is present and is usually persistent. The condition is often not diagnosed before the operation. The following case may be of interest:

Mrs. D. was admitted to the hospital with all the signs and symptoms of an acute septic peritonitis. Four years prior I had seen her in consultation during an attack of acute cholecystitis. The abdomen was opened through the right rectus. The appendix was delivered and found to be very hyperemic, but not seriously enough diseased to be the causation of the signs and symptoms presenting; it was however removed. Examination of the abdomen through the incision revealed a gall bladder full of stones. The incision was prolonged upwards and an acute hemorrhagic pancreatitis was revealed by numerous patches of fat necrosis on the peritoneal surfaces of the intestines and flame shaped hemorrhages into the mesocolon and neighboring organs. The peritoneum was reddened. The pancreas was increased in size and boggy, but no fluctuation was detected. An opening was made through the mesocolon and the finger plunged into the substance of the pancreas; a cigarette drain was inserted into the rent in the pancreas and brought out through the mesocolon and the lower end of the abdominal incision; this drain was surrounded by other cigarette drains with the idea of protecting the general peritoneal cavity from any possible pancreatic drainage. The gall bladder was emptied of a large number of stones and concentrated black bile, and drained by an implanted tube. The convalescence was somewhat stormy, but eventually the patient made an excellent recovery, and was discharged from the hospital in a little over four weeks from the time of the operation. The peritoneum in this case was very much injected but not infected.

In acute inflammation of an intestinal diverticulum the signs and symptoms are similar to those of an acute appendicitis, with the exception that the localization depends upon the situation of the diverticulum.

In typhoid fever the onset is insidious, and is not preceded by an acute intraabdominal lesion, as in an acute septic peritonitis. The temperature and pulse rate are elevated. Vomiting, if present, is not a prominent feature. Diarrhea is usually but not always present. A distinct gurgling in the right iliac fossa is very often to be detected by palpation. Distention may be marked, but it is not associated with much spasm of the abdominal muscles, as is seen in acute septic peritonitis. Red rose spots and enlargement of the spleen are not evident in the early stages of the disease. Blood examination shows a leukopenia, except where a secondary bacterial infection of the ulcers occurs, and in those cases we may have a leukocytosis. The Widal reaction is usually negative in the early stages of typhoid, but a blood culture is positive after the second or third day of the disease. Abdominal pain is not a prominent symptom.

In mesenteric embolism and thrombosis the onset may be sudden or insidious. Before distention makes its appearance a tumor may be made out. Bloody mucus is passed from the rectum, and even a diarrhea may be present. The vomiting is not urgent. There may be signs of pre-existing cardiac disease; there may be thrombosis in other parts of the body.

In acute lead poisoning the prominent features are widely spread colicky pain, relieved by pressure, obstinate constipation and collapse. Abdominal distention and vomiting are not marked features. There is the typical blue line on the gums.

In acute renal infections the onset is sudden and accompanied by pain, which is most marked in the costovertebral angle of the affected side. Vomiting, if present, is not persistent and urgent as in an acute septic peritonitis. There may be some colonic distention, but this is not associated with spasm of the abdominal muscles. In a pyelitis, examination of the urine shows pus cells and bacteria; this also obtains in other nephritic infections when the focus is draining into the pelvis of the kidney.

In renal colic the onset is sudden and accompanied by severe cutting pains, and very often by nausea and vomiting. The pain is reflected down the affected side, in the male to the tip of the penis; tenderness is to be made out by palpation in the costovertebral angle of the affected side. Very early the urine shows red blood cells. The vomiting is not severe, and it is not, as a rule, persistent. There is no distention. There may

be spasm of the abdominal muscles of the affected side.

In biliary colic the onset is sudden and accompanied by severe pain in the upper right quadrant, and very often by nausea and vomiting. The muscles on the right side of the abdomen may be in a state of spasm. There may be some distention of the colon. A tender tumor in the region of the gall bladder may be made out very often. Jaundice may be present, or the history of a previous attack followed by jaundice; where jaundice is present biliary salts may be found in the urine, and the stools may be clay colored.

The differential diagnosis between acute intestinal obstruction, intestinal paresis, and acute septic peritonitis is peculiarly of very great importance. As already pointed out, an acute septic peritonitis may be the end picture of either an acute intestinal obstruction or an intestinal paresis. An acute intestinal obstruction may arise during the course of an acute septic peritonitis, and on the prompt diagnosis of such depends the patient's life. In all cases of acute septic general peritonitis, which do not resolve, the end picture is an intestinal paresis. In acute intestinal obstruction, whatever the etiologic factor may be, the onset is usually like a bolt out of a clear sky, whereas in acute septic general peritonitis there is usually some good and definite cause for its occurrence. The facial expression from the onset is one of anxiety, the features pinched and pale, the hands and feet are cold, and the body is covered by cold, clammy sweat. The temperature is subnormal. The pulses are rapid, thready, and weak. Early in the case, the abdominal muscles may be soft, and the coils of intestines, in a state of tonic spasm, may be seen and palpated, giving rise to a lattice-like effect; as the case proceeds, the abdominal muscles become rigid and distention makes its appearance; in acute septic peritonitis, muscle spasm is a prominent feature from the onset. The stethoscope, applied to the abdomen, reveals active peristalsis; early in the case of acute septic peritonitis, active peristalsis can also be demonstrated in a similar manner, but later on, as the intestines become paralyzed, nothing can be heard by the stethoscope; this latter phenomenon also obtains in other forms of intestinal paresis. Vomiting is a constant symptom and probably the most important one of acute intestinal obstruction; as the disease progresses, it increases in severity and becomes urgent and projectile in character; at first the vomiting is from the upper gastrointestine, is mixed with bile and has a sweetish odor; this is soon followed by the contents of the small intestine, and the odor is foul and putrid. The occurrence of projectile vomiting is, in my opinion, the most valuable aid in the diagnosis of acute intestinal obstruction. The vomiting in an acute septic peritonitis is urgent, but it is seldom projectile in character, unless the disease has become complicated by the development of an obstruction. The temperature in acute intestinal obstruction, in the beginning, is subnormal, and as the case proceeds, is further depressed, except in those cases in which a general peritonitis has developed, when there may be an elevation; and this, in progressive cases, does not last very long, the temperature becoming subnormal again, as the result of an overwhelming toxemia. Early in the case of acute intestinal obstruction the lower bowel may be emptied; this, however, is soon followed by complete stoppage of the passage of gas and feces from the rectum; in cases due to intussusception, bloody mucus may be passed from the rectum. In the case of a strangulated external hernia, we have an irreducible protrusion through a hernial opening. In paralysis of the intestines, following abdominal or other grave operations, or occurring during the course of a pneumonia and other acute diseases, the facial expression is not that of great anxiety. The pulses are rapid, but not extremely so. The temperature may be slightly depressed. In the early stages of intestinal paresis there is not the extreme toxemia of acute septic peritonitis or acute intestinal obstruction, but as the disease progresses the peritoneum becomes infected in a manner similar to that met in the late stages of obstruction. In paralysis the vomiting is regurgitant in character and may be persistent; it is not urgent, as in septic peritonitis, or projectile, as in acute obstruction. Distention may be excessive, but it is not associated with much spasm of the abdominal muscles.

In the question of the treatment of acute septic peritonitis one must necessarily take into consideration the primary lesions leading up to the infection of the peritoneum, and one may discuss it under three headings: (1) The treatment of the primary lesion. (2) The treatment where localization has occurred. (3) The treatment where localization has not occurred.

1. The treatment of a primary lesion may be regarded as one of prophylaxis, since one may say that in each of the inflammatory conditions occurring within the abdomen, in a gastrointestinal perforation, in an acute intestinal obstruction, in a mesenteric embolism or thrombosis, and in an intestinal paresis, we have a potential acute septic peritonitis. The treatment is obviously the relief of the primary lesion, and need not be discussed in this contribution.

2. The treatment where localization occurs: In some of the cases of acute septic peritonitis there is a distinct tendency to localization, and this is especially true in the case of pelvic inflammations. The following case may be of interest:

I was called in consultation to see a patient suffering from an acute abdominal disorder. On arrival, I found the following conditions: The facial expression of the patient was one of great anxiety. The temperature was high. The pulses were rapid, thready and intermittent. The abdomen was greatly distended and exceedingly tender. The breathing was rapid and shallow. The patient complained of great pain in the right chest upon deep inspiration. Vaginal examination revealed a discharge from the cervix, and the uterus was held fixed by a sensitive mass in each broad ligament. The cardiac action was irregular, with a systolic murmur at the apex. Examination of the chest revealed a basal pleurisy on the right side. She was evidently suffering from an extreme degree of shock, and operation was out of the question. Two and one-half grains of morphine were given in the first four hours, and thereafter one-quarter grain every two to four hours, as occasion demanded, for several days. Fisher's solution with 10 per cent. glucose solution was administered by the Murphy drip. Ice packs were applied to the abdomen. On the fourth day, she

passed flatus, on the following day, she had a copious bowel movement, and thereafter made an excellent recovery.

Where localization is taking place everything should be done to assist in the building up of the barrier between the infection and the general peritoneal cavity; practically the same régime should be carried out as will be described later in dealing with the question of acute septic general peritonitis. As already pointed out, the process may end in resolution, or it may go on to the formation of an abscess. Drainage is, of course, necessary in cases going on to abscess formation, but operation should be delayed sufficiently long to allow organization of the barrier between the focus and the general peritoneal cavity, and then nothing more than simple drainage should be attempted.

3. The treatment where localization has not occurred: Where localization is not evident, and is not expected, early operative interference is imperative, as it is very evident that the causative factors must be eliminated before one has any chance in the treatment of the peritonitis; thus a gangrenous appendix, intestinal diverticulum or gall bladder, whether perforation has occurred or not, must be removed; a gastrointestinal perforation must be closed; an acute intestinal obstruction must be relieved; and, where indicated, adequate drainage must be provided for. Following the operation my routine treatment for these cases is as follows: The patient is placed in the Fowler position and intra-abdominal drainage encouraged toward the pelvis, where lymphatic absorption is at its minimum. Bartlett in his recent work, "After-treatment of Surgical Patients," advocates that the patient be placed in the position most advantageous for drainage; while this appeals to me as a very sensible procedure, I have not as yet used it.

To combat the shock the peristalsis with its resulting pain and vomiting must be stopped; and this can be done by the free use of morphia. Morphia is given hypodermically and should be pushed to the physiologic limit, in order to splint the intestines; to do this large doses are necessary. I have often given to an adult patient two to three grains of morphine in four to five hours and thereafter sufficient to keep him under the influence of the drug until the vomiting has ceased, the abdomen has become soft, and flatus has been passed freely. In order to use morphia in this heroic manner one must have courageous and conscientious nurses, who are thoroughly familiar with the mode of treatment; the respirations should be kept in the neighborhood of twelve per minute; in the most desperate cases even as low as eight per minute; the frequency and character of the pulse and the urinary output should be kept under the most careful observation.

To combat the acidosis arising from the dehydration, etc., Fisher's solution with 10 per cent. solution of glucose is given per rectum by the Murphy drip method; this, by supplying fluid to the circulation, dilutes the circulating toxins, protects the alkaline reserve in the blood, and, by increasing secretions and promoting diuresis, aids in the elimination of the toxins. Occasionally, on account of the intestinal irritability, we find that the rectum will not retain the fluid in the early stages of the treatment. Under such circumstances sterile normal salt solution is supplied by hypodermoclysis until the rectum becomes tolerant, which occurs as soon as the patient is fully under the influence of the morphia; thereafter the drip method is continued more or less continuously for several days, according to the rectal tolerance. No fluid is given by the mouth as long as the symptoms are acute, but is commenced just as soon as the vomiting ceases, which occurs when the patient is fully under the influence of the morphia; it is given at first in small quantities at the temperature of the room, and the amount is increased gradually as gastric tolerance is shown. Some surgeons hold that fluid should be withheld both by rectum and by mouth, and that fluid should be supplied only by hypodermoclysis, but I have found by experience that the régime as above outlined works out practically very well. It is wise during the forcing of fluid to remember that a patient may become water-logged, and, therefore, the lungs should be kept under observation for any possible edema. During the course of treatment the blood and urine should be kept under careful observation for a diminishing alkaline reserve. Where full laboratory cooperation is not possible, I find that watching the amount of urine and its general characteristics gives a very fair index as to the amount of alkaline reserve in the blood. However, where possible, it is wise to have the full cooperation of a competent pathologist in the treatment of these cases. If an acute acidosis is pending I diminish the morphine and increase the administration of fluid; in desperate cases where suppression of urine seems imminent I give Fisher's solution intravenously and administer theocin or diuretin hypodermically. The following case, reported in more or less detail, may be of interest:

R. M., a girl, eleven years of age, was admitted to the hospital with the following signs: Temperature 102.6°; pulses 126; abdomen distended, muscles rigid, tenderness being most marked on the right side; leucocytes 17,000, with 85 per cent. polynuclear cells. The abdomen was opened through the right rectus, and a perforated gangrenous appendix and a general peritonitis found. During the incision of the peritoneum, the cecum was accidently opened and the wound was immediately flooded by fluid feces, swarming with pin worms. The opening in the cecum was closed, the appendix removed and drainage provided for. During the first 24 hours after the operation the rectal temperature rose to 105.6; the pulse rate increased to 165; vomiting was present but not excessively so; the patient became delirious and had to be restrained; the amount of urine passed was 17 ounces. One and three-fourth grains of morphine were administered hypodermically in ¼ grain doses during the 24 hours. The Murphy drip of Fisher's solution and glucose was not retained, and, consequently, a pint of normal saline was given by hypodermoclysis. During the second 24 hours after the operation, the condition continued grave: Morphine was increased to 2 grains in ¼ grain doses; the Murphy drip was not being retained very well and, so, a second hypodermoclysis of normal saline, one pint, was administered. During the 24 hours, the delirium became less, 24 ounces of urine were passed, and the temperature and pulse rate commenced lowering; vomiting ceased; some flatus was passed. During the third 24 hours after the operation 2 grains of morphia were given and the

patient's condition improved considerably; the delirium ceased; the temperature and pulse rate continued to fall; 25 ounces of urine were passed; small quantities of water were retained by the stomach; flatus was passed freely. During the fourth 24 hours after operation the improvement continued and it was only necessary to give ⅛ grain of morphia; she was allowed water freely by mouth. During the fifth 24 hours after the operation the temperature was 99 and the pulse rate 70; morphia, in one dose of ⅛ grain, was given for the last time. During the seventh 24 hours after the operation the patient had a copious bowel movement. She was discharged from the hospital in 29 days from the date of the operation.

Throughout the course of the treatment of an acute septic peritonitis the character of the vomiting should be carefully observed, as an acute intestinal obstruction may develop at any time. As already pointed out under the caption of diagnosis, the vomiting of acute septic peritonitis may be urgent, but it is seldom projectile in character. The following case is illustrative:

J. C., a boy, seven years of age, was admitted to the hospital and operated upon for a perforated gangrenous appendix, complicated by an acute septic general peritonitis; the appendix was removed and adequate drainage provided for. Under treatment, the patient was apparently convalescent. On the eighth day after operation vomiting recurred and quickly became projectile in character; the abdomen became distended again and his general condition rapidly became critical. The abdomen was reopened through the former incision, and a large evil smelling abscess found and drained. The projectile vomiting immediately ceased and, thereafter, he made an excellent recovery.

The treatment, as outlined above, when scientifically and thoroughly carried out, is not only efficacious but a very humane one; when the patient is fully under the influence of the morphine he loses that anxious, pinched look, which is so characteristic of a general peritonitis, the vomiting ceases, the pulses become slower, softer, and of a better quality, the abdomen becomes soft, and flatus is passed on the third or fourth day, and the bowels move of their own accord a day or so later. Even where the case ends fatally, and some of these cases are fatal whatever one does for them, the patient is spared the terrible torture that is suffered by patients dying from acute septic peritonitis without the aid of morphia.

In reviewing my private case records I find that appendicitis is the most common cause of acute septic peritonitis occurring in my practice. In the last 150 operations for appendicitis 28 were for gangrenous appendices; three deaths occurred, giving in the total number of cases a mortality of 2 per cent. It may be of interest to give a brief résumé of the fatal cases:

First death—G. S.—Patient had been ill for nearly three days before admission to the hospital. At the time of operation it was found that the appendix was gangrenous and perforated, with a widely spread general peritonitis present. Ten days after the operation the patient was making an excellent convalescence when he had a severe intra-abdominal hemorrhage. He was transfused and no further bleeding occurred. Following the hemorrhage, however, his condition commenced retrogressing; distension and vomiting reappeared; and he died on the fourteenth day after his operation. Post mortem examination showed that the hemorrhage had come from the great omentum, which had become gangrenous in the neighborhood of the cecum; that the cecum and ascending colon had become gangrenous; that the right side of the abdomen was filled with putrid blood clot; that there was a large putrid abscess behind the cecum and liver.

Second death—H. S.—Attack commenced two days before admission to the hospital. A widely spread and virulent general peritonitis, in addition to a perforated gangrenous appendix, was found at the operation. His condition continued to get worse and he died thirty hours after the operation.

Third death—B. B.—Man aged 72 years. Operation took place within twelve hours of the onset of the disease; a perforated gangrenous appendix was found. Following the operation he had a brisk general peritonitis, which subsided under treatment. On the seventh day after operation he developed an acute mania, from which he recovered. On the tenth day he was apparently convalescent. On the thirteenth day his wound opened and omentum presented; this was reduced, and the wound was strapped. Thereafter, his condition became grave, and he died on the fourteenth day after operation.

288 Linwood Avenue.

LARYNGOPULMONARY TUBERCULOSIS.*

By JULIUS DWORETZKY, M.D.,

Liberty, N. Y.

Tuberculosis of the larynx is always secondary to tuberculosis of the lungs or lymphatic glands. There are a number of instances where laryngeal tuberculosis is reported as a primary affection, but the author in all his experience never saw a case of primary tuberculosis of the larynx. Occasionally, however, we do meet a case of laryngeal tuberculosis without any definite signs of the disease in the chest, but a diligent study will always discover the primary focus in the lungs or in the thoracic glands. If the larynx were involved primarily and alone the treatment of the lesion would be very fruitful, and in the vast majority of cases would be crowned with success: First, because of the accessibility of the larynx and the ease with which it could be treated; and second, because of the high tendency to fibrosis that tuberculous tissue possesses. The reason for the poor prognosis in laryngeal tuberculosis is chiefly because of the underlying trouble in the lungs. We all know of cases where the trouble in the larynx was cured by local treatment. But in such cases we invariably find that the pulmonary lesion was either slight or else inactive. Where the lesion in the lungs is active and a laryngeal complication exists, regardless of the type of the laryngeal lesion, the prognosis is very poor.

It would therefore seem insufficient to treat the lesion in the larynx as an affection *per se*, and the author is of the opinion that a case of laryngeal tuberculosis should always be spoken of and treated as laryngopulmonary tuberculosis. For only by treating the lungs primarily may we hope for success, and for this reason the writer feels that laryngeal tuberculosis should never be treated in the office or clinic, except where the pulmonary lesion is inactive or where distressing symptoms have to be relieved. It is not the author's desire to discourage the laryngologist from treating laryngeal tuberculosis, but rather to stimulate his interest in pulmonary tuberculosis and to impress on the mind of the laryngologist the importance of such work.

*Résumé of studies, based on eight years' experience in institutions and private practice. Submitted as thesis for candidacy to the American Laryngological, Rhinological, and Otological Society, November 1, 1920.

Etiology.—Tuberculosis of the larynx is almost invariably found among tuberculous adults, and occurs in about twenty-five per cent. of the patients. It is extremely rare among children and the writer can recall only one case of laryngeal tuberculosis in a child of the age of eight. It is also present only in those cases which have, or have had, a positive sputum. In the repeated absence of tubercle bacilli in the sputum the diagnosis of laryngeal tuberculosis should always be made with reservation. From a study made in 1913-1914, the writer found that in the vast majority of cases of laryngeal tuberculosis there was usually present some predisposing cause, such as nasal obstruction, chronic pharyngitis, tonsillitis, catarrhal laryngitis, history of excessive cough, excessive use of tobacco and alcohol, and lues. The infection, in the writer's opinion, is caused directly by the tubercle bacilli implanted on the mucous membrane of the larynx. Let us bear in mind that in almost every case of laryngopulmonary tuberculosis we have an open pulmonary lesion which means a constant stream flowing over and bathing the laryngeal mucosa. The anatomy of the interior structures of the larynx is very complex, and pus travelling over it is bound to become stagnant and thus adhere to the minute folds of the mucous membrane. Healthy mucous membranes may be able to resist it by its natural immunity, but when inflamed the intercellular spaces become widened, and the bacilli, not meeting with any resistance, enter the mucosa and submucosa, thus setting up a tuberculous inflammation.

Clinical Types.—There are three distinct types of laryngeal tuberculosis; the acute, the subacute, and the chronic, each one of the types having a course of its own. The acute type is characterized by a soft edema of the larynx with a marked tendency to ulceration. It may begin acutely or else follow the subacute or chronic type. It usually occurs in advanced pulmonary cases, often in moderately advanced, and occasionally in an incipient case. There is little or no tendency to fibrosis and it, therefore, takes an acute course. Nodules, consisting of tubercles, can often be seen above the surface of the mucosa. When the tubercles caseate, they give rise to ulcers. During the stage of caseation the nodules often coalesce with the production of extensive ulcerations. The patient usually suffers from marked hoarseness or aphonia, sensation of fulness in throat and irritation with constant desire to cough and expectorate. Dysphagia is of common occurrence, and may be very pronounced, depending largely on the location and character of the ulcerations. With the patient in good general condition it may run its course, become subacute and occasionally arrested, but in general the lesion is hardly amenable to treatment. As to prognosis, the life of the patient is generally from six to eighteen months. It is often a terminal condition in advanced pulmonary cases, especially in patients who are overwhelmed by the toxins of the tubercle, and who have completely lost the acquired immunity to the disease.

The subacute type is characterized by a pseudoedema of part or parts of the larynx with a moderate tendency to fibrosis. It may begin as such or else follow the acute or chronic type. It takes a subacute course, has a tendency to fibrosis and is usually benefited by treatment. Papiliform infiltrates and soft polypoid excrescences usually belong to this type. The local symptoms may be slight or moderate, depending largely on the extent and site of the lesion. Hoarsness, as a rule, is present, particularly when the true cords or the interarytenoid sulcus is involved. Dryness in the larynx is usually complained of, especially when the fibrosis is extensive. With the patient in good general condition it runs its course and may become completely arrested. The prognosis as to life and voice depends much on the patient's general condition, and on an early diagnosis. With proper treatment the prognosis in the average subacute case is favorable.

The chronic type, which offers the best outlook, is characterized by firm infiltration of part or parts of the larynx with a marked tendency to fibrosis and healing. The lesion, due to an excessive proliferation of connective tissue cells, is usually limited in extent in the affected areas, and may remain so for an indefinite period. These patients suffer very little, and often, with the exception of occasional dryness in the throat and slight hoarseness, have no symptoms at all. For this reason *this type is very often overlooked.* The prognosis as to life and voice is very good, and unless the lesion takes on the course of the acute or subacute type the complication will have very little influence on the pulmonary condition. The diagnosis of this type, however, is of major importance. The patient should be told of the condition, so that the proper measures may be taken. Abuse of the larynx will often modify its course, while with proper attention this condition will usually remain secondary to the pulmonary lesion.

The three types just described, although one type may follow or precede the other, are undoubtedly distinct, and it is a highly essential to differentiate them because of the bearing on prognosis and treatment. As a rule, more than one examination will be required to make the proper diagnosis and to determine the course of the disease.

Diagnosis.—It is unfortunate that in the majority of instances the diagnosis of laryngeal tuberculosis is made after the lesion has become considerably advanced. This is usually due to the fact that the larynx of the tuberculous individual is not scrutinized more carefully. It should be borne in mind that the development of the laryngeal lesion is often very insidious and without any troublesome symptoms, and by delaying the examination of the larynx till the patient complains of symptoms, the lesion, as a rule, will have reached an advanced stage. In previous studies the writer found laryngeal tuberculosis in one out of four pulmonary patients, and it is his opinion that the larynx should be examined in every tuberculous individual, and only thus could early involvement be discovered. We must never forget that the respiratory tract does not begin at the apices of the lungs. The examination of the respiratory tract should always begin with the nasal chambers and an examination of the lungs, no matter how thorough, without an examination of the upper respiratory tract should be considered incomplete. As in most other diseases, these patients present subjective and ob-

jective symptoms. The subjective symptoms are those caused by the lesion in the larynx as well as those associated with the pulmonary lesion. The objective symptoms are those of pulmonary tuberculosis and the physical findings on laryngoscopic examination. In this paper laryngeal symptoms and signs only will be considered.

Subjective Symptoms.—The symptoms of tuberculosis of the larynx can be conveniently divided into two groups; first, those of the early stage, and second, those of the moderately advanced and advanced stages.

The most common symptom in cases of early disease is hoarsness. It often begins with slight huskiness of the voice in the morning, gradually disappearing during the course of the day. It varies from a slight change in the voice quality to a low pitched rasping sound. The onset of the hoarsness is, as a rule, insidious in the chronic cases, while it is more sudden in the acute and subacute cases. When the onset is insidious, the patient is often unaware of the development of this symptom, and only by careful questioning can the date of the onset be established. In early cases the hoarseness is most commonly due to infiltration of the posterior commissure or of one or both cords, and often to a combination of both. Cases with marked papillomatous growths in the upper portion of the posterior commissure with no alteration in the quality of the voice are often seen. Thus the hoarsness depends largely on the location of the tumefaction. If it is above or below the cords, the voice may be quite normal.

The most frequent symptom, or rather combination of symptoms, is the sense of discomfort in the larynx. This sensation is vaguely and variously described as a lump in the throat, desire to clear the throat before talking, consciousness of the throat, irritation as if caused by a hair lodging in the throat, dryness, hypersecretion, burning, rawness, sticking pain, etc.

Dysphagia, dysphonia, and aphonia are uncommon among early cases of tuberculous laryngitis. The symptomatology in more advanced cases of laryngopulmonary tuberculosis is more definite and often pathognomonic. Hoarseness is almost always present when the involvement is extensive, and the classic symptoms, such as dysphagia, aphonia and dysphonia, although more common than in the early stages, are less common than generally supposed.

Objective Symptoms.—The physical findings in tuberculous laryngitis will depend, first, on the stage of the disease, whether early or advanced; second, on the type of the lesion, whether acute, subacute or chronic. Early or incipient cases are characterized by infiltrative changes; the advanced cases by extensive infiltration with ulceration. The various types of laryngeal tuberculosis have already been described.

Pathological Manifestations.—Anemia of the Larynx.—This is often spoken of as a sign of tuberculosis. This manifestation is present in acute cases in which there is formation of tubercles, marked edema and interference with circulation. The acute type of laryngeal tuberculosis, however, is not the most common type. When anemia is present in other than acute cases, it is usually due to a general anemic condition of the patient.

Congestion.—This condition is more common than anemia. It is present in the great majority of the subacute and chronic cases. The congestion may be due to a catarrhal condition preceding the tuberculous lesion, or may be caused by the tuberculous lesion itself.

Infiltration.—By this term is implied inflammatory changes caused by the tubercle bacillus. The part affected is congested and increased in size. The edema may be either of the soft variety, such as seen in the acute case, or of the hard indurative kind, as seen in the subacute and chronic cases. Soft edema occurring in the arytenoids usually produces the characteristic pear-shaped swelling. When the process is chronic, there is a marked proliferation of connective tissues, and the infiltration becomes hard. Infiltration is most common in the posterior segment of the larynx, but may be seen elsewhere.

Ulceration or Necrosis.—Degeneration of tissue usually occurs after tubercles coalesce and caseate. A typical recent ulcer has a grayish appearance, while a chronic ulcer may be red due to the formation of granulations. Ulcers are most commonly seen at the posterior portion of the vocal cords, the vocal process, the posterior commissure, and the rim of the epiglottis.

Tumefaction.—This may appear before or after ulceration takes place. Tumefaction before ulceration is usually due to edema, and is most common in the arytenoids, the ventricular bands, the laryngeal surface of the epiglottis and the aryepiglottidean folds. When it follows ulceration, it usually takes the form of granulations, papillomas or tuberculomas. Granulations are most common when ulcerations are present. Papillomas and tuberculomas usually occur at the posterior commissure.

Lesions.—The frequency with which a part of the larynx is found to be affected is in direct proportion to the amount of trauma that part receives as a result of its functional activity and its location.

Interarytenoid Space.—The earliest and most frequent seat of disease is the posterior commissure. The earliest change in the posterior commissure consists of hyperplasia of the mucous membrane. On partial approximation of the cords, this hyperplastic mucous membrane takes on a wrinkled appearance. A streak of mucopus is often seen adhering to the space; but this merely signifies that there is a discharging focus in the lungs. It is often present without any demonstrable tuberculous lesion in the larynx. The usual color of the hyperplastic mucous membrane is gray, although occasionally it is red. As the lesion progresses, a median furrow is formed which is readily perceived on a partial approximation of the cords following a deep inspiration. At this stage a lateral furrow, as described by Casselberry (Casselberry, W. E.; The Recognition of Early Changes in the Larynx in Tuberculosis. *Journal A. M. A.*, Nov. 15, 1913, p. 1789), is also frequently observed. The formation of these furrows is due to the constant creasing of the diseased mucous membrane during all respiratory acts. A little later, if the disease is not arrested, the process will go on to ulceration. The ulcers are usually shallow and of gray appearance. Often there is an exurberance of granulations with

the formation of papillomas or tuberculomas. The papillomas vary in size and shape, but are usually of the broad base type. The amount of discomfort caused by a papilloma in the space depends on its location. If situated right between the true cords, the symptoms, such as hoarseness, aphonia and dysphonia, are marked, while if situated above or below the cords, symptoms may be lacking. Patients with papillomatous growths in the space almost always clear the throat before talking. This is usually due to the presence of the growths or to the streaks of mucopus adhering to its rough surface. Conditions such as nasal stenosis, chronic pharyngitis, accessory sinusitis, bronchiectassis, lung abscess, syphilis and asthma will cause a hyperplasia of the posterior commissure simulating tuberculosis. When these conditions, however, are eliminated, interarytenoid hyperplasia with or without ulceration is pathognomonic of tuberculosis of the larynx.

Vocal Processes.—The portion of the larynx next most frequently affected is the vocal process, or the anterior angle of the arytenoid cartilage, which gives attachment to the vocal cords. The vocal process is found frequently affected in early cases, and is therefore considered separately. The proximity of the vocal processes to the arytenoids, true cords and interarytenoid space, with the consequent liability to trauma, renders them a favorable site for the development of the lesion.

Arytenoid Cartilages.—The arytenoids are next in frequency of involvement. Infiltration of the arytenoids varies from slight swelling, which appears hard, or semiedematous, to large edematous masses, partially obstructing the opening into the larynx. Marked edema of the arytenoids with extension into the folds gives the characteristic pear-shaped appearance.

Vocal Cords.—The usual site of the lesion is at the posterior portion of the cords. The anterior portion is often involved together with the posterior portion, but very rarely is the lesion limited to the anterior portion. Lesions of the cords do not differ in their appearance from a lesion located at any other part of the larynx. Descriptive terms such as "mouse-eaten," "granular" and "cleft-like," are often used in speaking of these lesions.

Epiglottis.—The epiglottis is the first portion of the larynx that comes into view on laryngoscopic examination, and its lesions are therefore most easily located. Infiltration is the most common manifestation. The site of the lesion is either at the rim or else at the cushion. Epiglottidean lesions are usually bilateral and more or less diffuse.

Ventricular Bands and Arepiglottidean Folds.—The most common affection of the above structure is manifested by infiltration.

Differential Diagnosis.—In discussing the differential diagnosis, only those conditions that are not described at length in textbooks will be considered here.

Bronchiectasis and Lung Abscess.—A large majority of patients with bronchiectasis or lung abscess present an appearance in the larynx typical of tuberculosis. The pulmonary condition of these patients being unknown at the time of the examination, the laryngeal lesion is classified as tuberculous. The diagnosis is changed only when it becomes established that they are suffering from a nontuberculous pulmonary infection, and the larynx would unlikely be tuberculous.

Accessory Sinusitis.—These cases often present an appearance in the larynx that may lead one to believe it tuberculous. In these patients there is usually a marked thickening at the posterior commissure and often at the posterior ends of both cords. The thickening is undoubtedly caused by the purulent discharge from the posterior nares, and by the improperly modified air breathed in through atrophic nasal chambers; a condition which usually accompanies chronic accessory sinusitis. In such cases, a thorough examination of the nasal chambers and sinuses will help in establishing the diagnosis of the laryngeal lesion.

Laryngitis Sicca.—This condition often accompanies accessory sinusitis, atrophic rhinitis and nasal obstruction. The lesion in these cases is diffuse, and here, also, the diagnosis may be determined after a thorough examination of the upper portion of the respiratory tract. If, however, in addition to one or more of the three previously described conditions the patient also has a positive sputum, he should be carefully watched, for the resistance of the larynx having been lowered, it is readily subject to infection by the tubercle bacillus, and any signs of progress of the lesion should be regarded as evidence of clinical tuberculosis.

Lupus.—When occurring in the larynx, this disease is characterized by a warty growth, very little ulceration and marked fibrosis. While tuberculosis of the larynx is usually secondary to tuberculosis of the lungs, lupus of the larynx is supposedly secondary to lupus of the skin. The writer, however, reported a case of lupus of the larynx where the lesion was apparently primary. (*Journal A. M. A.*, August 25, 1917, lxix, pp. 619-624.)

We must also differentiate tuberculous laryngitis from hypertrophic laryngitis, syphilis and carcinoma.

Prognosis.—The prognosis may be discussed in regard to (1) life and (2) voice. As a rule both are intimately connected, except in chronic cases, in which the voice may remain affected while the length of the patient's life is generally not affected.

The factors that determine the prognosis as to life are:

1. *The Pulmonary Condition.*—The character and extent of the pulmonary lesion should be carefully studied. The chronic type of pulmonary tuberculosis is the most favorable and the outlook here is good, while in the acute and subacute cases the prognosis is more serious. Patients with the most extensive lesions do not give the poorest prognosis. One with a widely spread fibroid lesion invariably offers a better prognosis than a patient with a limited subacute or acute lesion. In other words it is not so much the extent as the charcter of the lesion that determines the gravity of the individual case. Of course a small lesion is of more favorable outlook than a more extensive involvement of the same type.

2. *General Condition.*—Temperature, pulse and weight constitute the keynote to the patient's general condition. A rapid pulse usually signifies myocardial degeneration caused by the toxemia from

the tubercle, and when present for a prolonged period renders the prognosis grave. Daily or frequent elevation of temperature for a considerable length of time shows that the case is either of the acute or subacute type, depending on the height of the fever. The chronic cases often have febrile exacerbations, which, however, last only a brief time. A continued sub-normal temperature is a bad prognostic sign. The patient's state of nutrition is also an important guide in the prognosis.

3. *Underlying Disease,* such as syphilis, undoubtedly aggravates the prognosis by lowering the general vitality of the patient.

4. *Type of Laryngeal Lesion.*—The prognosis in acute cases is poor, but occasionally we see such cases improve. In subacute cases the prognosis is much better. This is the type that is most amenable to treatment, and when other factors are favorable the prognosis is good. The chronic cases are the most hopeful. Here the voice may remain affected, but the length of the patient's life is generally not influenced. We must, however, bear in mind that any one of the lesions may suddenly change its course, and for this reason the prognosis should always be guarded.

5. *Location of the Lesion.*—The prognosis as to life is most favorable in cases in which the lesion is situated in the posterior commissure or on the true cords. Such lesions usually are of the subacute or chronic type and tend to heal by fibrosis. Lesions of the epiglottis, aryepiglottidean folds, arytenoids, and ventricular bands may be of the acute, subacute or chronic type, and the outlook here is less favorable. In other words, where the mucous membrane is closely adherent, such as on the true cords and posterior commissure, the disease takes a chronic course and the prognosis is therefore favorable. When the mucous membrane is loosely adherent, such as on the epiglottis, folds, arytenoids and ventricular bands, the course is usually more acute and the prognosis less favorable.

6. *The extent of the Lesion.*—This does not necessarily influence the prognosis as to life, although cases of slight involvement are the most hopeful cases as far as the voice is concerned; nor is the prognosis less favorable in cases with ulceration. In fact, local medication takes better effect when ulcers are present. Thus we may say that widespread lesions, unless of the acute type, do not necessarily indicate a poor prognosis as to life.

7. *Early Diagnosis and Treatment.*—It is evident that the earlier the diagnosis is made, and the sooner treatment is instituted, the more easily can the lesion be cured or checked in its progress. This applies especially to the subacute cases which are most benefited by treatment and also to the chronic cases. The local resistance in the chronic cases is naturally lowered. The patient is usually unaware of the condition, and by early diagnosis and proper instruction regarding the care of the larynx, a chronic lesion will often be prevented from becoming acute. The acute cases, which as a rule take their own course, are occasionally helped by an early diagnosis.

8. *Nasal obstruction or Disease.*—Sinusitis, pharyngitis, or tonsilitis tend to lower the resistance of the larynx and thus influence the prognosis.

9. *Environment.*—The economic condition of the patient is often an important factor. Tuberculosis is a protracted and tedious disease and it takes about three to five years to accomplish an arrest of the lesion. Ample financial resources are necessary to "cure" over such a prolonged period. It is evident that the patient of independent means, and one who is faithful to the treatment, offers a better prognosis than his fellow of insufficient financial resources, who, in order to obtain a livelihood, must return to business or manual labor after only a brief course of treatment.

In giving a prognosis as to life, therefore, all the above factors should be carefully studied. Although in a number of cases the lesion in the larynx runs a course independent of the lesion in the lung, in the great majority of the patients the laryngeal lesion serves as an indicator of the pulmonary condition; and an active process in the larynx generally indicates activity in the lungs. Not only is a thorough knowledge of all these factors necessary but the laryngeal lesion itself should be watched for a considerable length of time so that the course may be definitely determined. In cases in which the lesion in the larynx is the chief predominating factor and runs an independent course, the general prognosis will of course depend chiefly upon the condition in the larynx.

The prognosis as to voice is usually more definite. This will depend largely upon the extent, location and character of the local lesion. The more extensive the process the greater the probability that the voice will remain affected. Cases with involvement of the true cords and interarytenoid space give a poorer prognosis as to voice than if situated elsewhere in the larynx. The destruction of tissue is usually greater in the acute and subacute cases, and there the voice suffers mostly. Of course the other factors, such as early diagnosis and treatment, influence the local as well as the general prognosis.

In general, then, it may be said that no definite prognosis as to life can be made from the condition in the larynx alone. All factors should be carefully considered and the laryngeal condition should only serve as an aid in the prognosis.

Treatment.—The treatment of tuberculous laryngitis is (1) general, (2) prophylactic and (3) local.

(1) *General Treatment.*—The general treatment is of primary importance since it is generally admitted that tuberculous laryngitis is invariably secondary to pulmonary tuberculosis. By treating the larynx and disregarding the lungs, we actually ignore the main issue. It is not only futile but also detrimental to a patient with symptoms of toxemia to go to the office for daily treatment of the laryngeal condition. The lungs should receive our first attention, and activity in the lungs requires absolute rest. The larynx in such cases may be treated with the patient in bed but never otherwise. Only cases with no activity in the chest may be allowed some exercise and may therefore be treated in the office, and in these cases, too, we must never overlook the pulmonary lesion. The sanatorium is the ideal place, although a number of patients that are financially able could be successfully treated at home. The country, where plenty of pure air can be obtained, is undoubtedly the most desirable place of residence. The dry mountainous climate is the most agreeable in the great

majority of instances. Outdoor sleeping should be urged, and persistent "curing" on a porch with a southern exposure will often accomplish surprising results. The exercise should be well regulated, and prescribed as the activity in the lungs and larynx subsides. The diet should be full and nourishing, and we must always remember that good digestion is the greatest asset in tuberculous patients. The stomach should never be abused and the diet should be carefully watched and regulated. As a rule three good meals judiciously selected are sufficient. Nourishment between meals should be recommended to patients whose weight is not up to the standard, and who apparently benefit by it. The writer feels that the general treatment of the patient is far more important than the local treatment, and a patient receiving only local attention with half-hearted or no treatment for the pulmonary condition is not being properly treated.

(2) *Prophylactic Treatment.*—This consists of the removal of predisposing factors capable of producing a catarrhal condition of the larynx with a consequent formation of a favorable site for the implantation of the tubercle bacillus. The predisposing factors are (*a*) nasal obstruction or disease; (*b*) pharyngitis and tonsillitis; (*c*) frequent colds; (*d*) abuse of the voice; (*e*) excessive cough, and (*f*) local irritants, such as smoke, dust, tobacco and alcohol. All these factors have a deleterious effect on the larynx and if possible should be removed.

(3) *Local Treatment.*—No specific remedy has as yet been discovered for tuberculosis of the larynx. The remedy, which we hope will eventually be discovered for the cure of tuberculosis of the lungs, will also cure the larynx. We are familiar with the different remedies tried, such as formalin, lactic acid, argyrol, silver nitrate, iodoform, etc. The writer has tried most of them and found some cases to be benefited by one, some by another, while a good many improved without any treatment and healed spontaneously. The method of treatment giving the best results is as follows:

First determine whether the case is acute, subacute or chronic. If chronic, the patient only suffers from slight discomfort, such as occasional tickling, irritation, etc., he is treated with a spray of 5 per cent. menthol in olive oil at frequent intervals. If no discomfort is present, he is told of his condition, warned not to abuse the larynx in any way and no local treatment is advised. The acute and subacute cases are treated locally at regular intervals. Such patients are supplied with De Vilbiss atomizers and told to spray the larynx four or five times a day with an alkaline solution, followed by a solution of 5 per cent. menthol in olive oil. If properly used the larynx is thus kept clear of accumulated mucopus and the patient is relieved of much of the discomfort.

Rest of voice is imperative in the acute and subacute cases. Absolute silence for the acute cases, while the whispered voice may be allowed as the case gradually becomes subacute. The patients with lesions of the chronic type may use the voice without harm. Abuse of the voice should, of course, always be discouraged.

For topical application the remedy found to yield the best results is the solution of iodine in glycerin. It is of the greatest benefit in the subacute and also in some of the acute cases. The writer uses it in strengths varying from 1.5 to 7.5 per cent., and applies it directly to the larynx on a laryngeal applicator. He begins with the 1.5 per cent. three times a week, gradually increasing the strength as the patient develops a tolerance for the solution. The application should be made gently during quiet breathing, and the entire larynx may be covered with it by asking the patient to phonate while the applicator is in the larynx, thus squeezing the swab with the true and false cords. The swab is then immediately removed and the patient is told to breathe quietly, thus preventing a coughing spasm in the majority of instances. When the stronger solutions are used, and especially in case with fresh ulceration, the patient often experiences sharp burning for a few seconds. This can easily be mitigated by previously spraying the larynx with a 2 per cent. solution of cocaine. Under this treatment, the writer has observed infiltration to diminish, granulations to disintegrate and absorb and ulcerations to heal. The solutions of iodine should be in brown bottles with glass stoppers. The action of the iodine on the lesion is probably due to its penetrating and antiseptic properties. The tubercle is avascular and cannot be reached by drugs through the circulation, while iodine is known to have a special affinity for tuberculous tissue. The iodine may also possibly exert its beneficial effect by causing mild irritation, thus producing slight reaction. The following are the formulas used:

Solution Iodine No. 1.
℞ Iodine crystals ..... gr. $7\frac{1}{2}$
Potassium iodide ..... gr. 15
Glycerin q.s. ..... oz. 1

Solution Iodine No. 2.
℞ Iodine crystals ..... gr. 15
Potassium iodide ..... gr. 30
Glycerin q.s. ..... oz. 1

Solution Iodine No. 3.
℞ Iodine crystals ..... gr. $22\frac{1}{2}$
Potassium iodide ..... gr. 45
Glycerin q.s. ..... oz. 1

Solution Iodine No. 4.
℞ Iodine crystals ..... gr. 30
Potassium iodide ..... dr. 1
Glycerin q.s. ..... oz. 1

Solution Iodine No. 5.
℞ Iodine crystals ..... gr. $37\frac{1}{2}$
Potassium iodide ..... gr. 75
Glycerin q.s. ..... oz. 1

Cases with superimposed catarrhal laryngitis or tracheitis are distinctly benefited by the intratracheal injection of 5 per cent. menthol in olive oil at frequent intervals. It allays irritation, diminishes cough and facilitates expectoration.

For relief of pain in laryngeal tuberculosis orthoform or cocain before meals will usually enable the patient to eat his food without distress. When the dysphagia is apparently due to infiltration and ulceration of the epiglottis, even if the lesion is not entirely confined to the epiglottis, the patient will often be relieved of this troublesome symptom by an epiglottidectomy. This operation is absolutely indicated in cases where the lesion is limited to the epiglottis, and the patient's condition permits.

PROSTATIC OBSTRUCTION.*

By P. E. TRUESDALE, M.D.,

FALL RIVER, MASS.

THE subject of prostatism and its treatment commands attention because: (1) the agent of its relief and cure marks an outpost in the progress of modern surgery; (2) it is one of the most serious and distressing changes occurring in the genitourinary tract; (3) frequently it has to do with a very important class of individuals, men of advanced years, often carrying heavy business responsibilities, men whose lives are of great value in the community; (4) such men are prone to hang their faith rather tenaciously on old-fashioned remedies and proprietary drugs, a long life having induced an over-cautious regard of modern art, so that they are reluctant to accept surgical aid until everything else has failed; and (5) lastly, because all practitioners treat the disease, and over 30 per cent. of those among us who pass the age of fifty (Morrow, Diseases of G. U., p. 337) will have some degree of enlargement of the prostate gland, although perhaps not more than one out of three or four thus affected will suffer pronounced symptoms.

Prostatic hypertrophy, then, is an harrassing ailment of the second half of life. The exact period at which it begins varies considerably since its presence is not suspected until it interferes with bladder function. Bladder disturbances from this cause have been reported by numerous observers in patients under forty years, but the extreme interference with the exit of urine caused by enlargement of this gland does not occur commonly before the fiftieth year.

Two forms of hypertrophy are observed in practice, the benign and the malignant. The benign form represents an overgrowth of the normal elements, forming a fibroadenoma or a fibromyoma in the gland.

This overgrowth may predominate in either of the lateral lobes or in the central lobe. One of our recent cases gave a history precisely similar to that of bladder stone. There were frequent sudden interruptions of the stream during urination. Upon cystoscopic examination this proved to be caused by an enlarged pedunculated middle lobe which had acted as a ball valve. Then there is the sclerotic form, the rigid scarred prostate, only slightly enlarged and usually not showing adenomatous changes.

The explanation of the obstruction caused by overgrowth of the fibrous, muscular, and glandular elements is found in the projection of the new tissue from those surfaces of the prostate which offer the least resistance, the vesical and urethral faces, for these are not hemmed in by the same firm fascia that is found on the rectal and perineal boundaries. For this reason the so-called middle lobe often projects into the bladder and may be the sole cause of obstruction.

In the overgrowth of the gland, the prostatic urethra becomes elongated, deviated, and decreased in caliber, the vesicourethral orifice becomes elevated, and thus complete evacuation of the bladder becomes difficult, and eventually impossible. In addition there is obstruction to the return circulation of the bladder, since the vesical veins empty into the compressed prostatic veins. As a result of back pressure there develops a dilatation of the bladder, ureters, and kidney pelvis, which in turn produces a chronic passive congestion of the kidneys. In the course of time obstruction increases. Ammoniacal fermentation of the urine is thus favored. The use of the catheter becomes imperative, and following this we observe cystopyelonephritis, chronic uremia, a progressive diminution of the nitrogen output, and death. Hence it is evident that in the presence of any marked degree of prostatic enlargement, trouble in the entire urinary tract is inevitable.

Occasionally one finds the bladder in a healthy state even after long-continued use of the catheter, but this is exceptional. Bad infections are common and men who carry such secondary changes greatly shorten expectation of life. They can be made good surgical risks only after a long period of treatment. Squire's (*Surg. Gyn. and Obs.*, Oct. 1913) studies of a series of unoperated cases showed that 50 per cent. died within five years from the onset of obstructive symptoms where the catheter was not used, while 66 2 3 per cent. died within a period of two years and eight months of catheter life.

Carcinoma of the prostate is no longer considered to be rare. Careful pathological examination of all areas throughout the gland have frequently revealed the presence of unsuspected cancer. This occurs in the circumscribed form which develops within the capsule. The diffuse carcinomata invade the tissues outside the capsule and are usually detected by their induration and stony hardness. Formerly the unrecognized malignant cases would improve after operation for a period of a few months to a year and return with evidence of cancer invading the anterior wall of the rectum by contiguity.

Symptoms.—The usual local symptoms of prostatic obstruction consist of a difficulty in starting the flow of urine, feebleness of the stream, and the unduly frequent calls to urinate, especially at night, representing the so-called "irritable bladder.." Frequency continues with the amount of residual urine increasing until eventually the patient finds it impossible to respond to the call of urination. Hematuria is common. It is observed more often with benign hypertrophy than with malignancy, contrary to widespread opinion.

It is well to bear in mind that in the earlier stages and the midperiod of the disease, other general symptoms may obscure the urinary discomforts, such as nausea, loss of appetite, indigestion, dryness of the mouth, headache, pain in the back, or slight fever, all of which may be due to mild uremia.

The nature of this disorder may be unsuspected during the congestive period or at least very well tolerated until the period of partial or complete retention. After excessive eating or drinking, constipation or an attack of grippe, there is a sudden exaggeration of the mild symptoms, or a complete retention of urine. When put to bed and catheterized properly, diuretics and cathartics em-

*Read before the New Bedford Medical Society, March 9, 1920.

ployed, the symptoms subside, only to return again under similar provocations. When infection follows the use of the catheter there is ushered in all the symptoms of cystitis, as dysuria, fever, and burning pain referred to the lower abdomen and the lower lumbar region.

Inefficient renal function, which is by no means rare in prostatic obstruction, frequently causes digestive disturbances, such as anorexia, indigestion, constipation, slight nausea, and occasional vomiting. These symptoms may be associated with headaches, blurring of vision, and extreme nervousness.

Diagnosis.—The diagnosis is a very important phase of the problem connected with the disease. There was a time when the history plus the information obtained from examination of the urine and the rectal examination were the only diagnostic means. While these have not been supplanted by other agents, precision in diagnosis has been greatly enhanced by the use of the cystoscope.

It is of prime importance for the physician or surgeon to have an accurate picture of the entire genitourinary tract before he can treat his patient intelligently, not alone estimate the probable outcome of his efforts. One should employ every means at his command to determine the nature of the enlarged prostate. Whether the changes are due to simple hypertrophy, calculi, cancer, or tuberculosis, will have an important bearing upon the prognosis and treatment. Finally, lesions of the spinal cord should be carefully excluded.

The examining finger notes the size, smoothness, symmetry, and consistency of the prostate. Perhaps in the majority of cases the rectal examination gives adequate and satisfactory information. An enlarged, smooth, soft, symmetrical gland may be the cause of great disturbance by the presence of a large middle lobe. Through the cystoscope, the middle lobe when enlarged is readily seen. This instrument should be employed in every case because it enables the examiner to see distinctly the contour of the vesical surface of the prostate, and the condition of the bladder wall. Diverticula, calculi, ulcerations, and carcinomatous degenerations are thus observed. It is sometimes difficult to distinguish the benign from the malignant prostate by visual examination since long-standing infections may give the mucosa an appearance of carcinoma. Tuberculosis is best recognized by the cystoscopist, although this condition is usually accompanied by a thickening of the seminal vesicules and epididymis and the presence of acid-fast bacilli in the urine.

Cancer of the prostate, when advanced, can be recognized by the uneven hardness and nodular areas felt on rectal examination, the presence of enlarged inguinal glands, hematuria, cachexia, etc. These patients are in a state of incurability and except in borderline conditions, no special knowledge or experience is necessary to make the correct diagnosis. Cancer is probably curable in the early stage only, when the cell division is still within the capsule. In this stage it is rarely detected by the examiner, usually overlooked by the operator, and occasionally escapes the pathologist unless the latter habitually makes a thorough search of the specimen for cancer cells. The search for cancer is now given special significance because it has been demonstrated frequently at autopsy that the entire prostate gland is never removed, that a thin layer of gland structure always remains attached to the capsule posteriorly, and radium has proved a very potent agent in destroying any residual cancer tissue.

Treatment.—Naturally the most rational treatment is the removal of the prostatic obstacle to urination. This cannot be done always for reasons that are well known, such as tabes, pulmonary or cardiorenal disease, renal insufficiency, or cancer. Excluding these conditions, Braasch (*St. Paul Medical Journal*, Jan., 1915) and other urologists advocate prostatectomy whenever there is evidence of persistent residual urine.

When a physician is summoned to treat a case of prostatism, he usually finds the patient acutely ill from obstruction following long-standing interference with normal urination. Relief is paramount. Immediate operation would greatly imperil the patient's life. Mild measures may be adopted by the physician and often lead to success in relieving the patient. Under the circumstances one may first empty the rectum by a hot water enema, and follow this with a suppository containing ¼ grain of morphine. The patient is warmly covered in bed with the hips elevated. The anterior urethra is injected with warm sterile oil. A clean, soft catheter is filled with oil and introduced. Should this effort fail, an elastic coudé catheter, No. 10, Eng. is tried and usually enters the bladder. In exceptional cases, all instrumentation per urethram fails, and this should not be continued long enough to exhaust the patient or inflict damage to the soft parts, for superpubic aspiration of the bladder can be done under local anesthesia or gas-oxygen speedily and with most satisfactory consequences. Subsequent drainage by the superpubic route is far more comfortably borne and controlled. At the outset, then, one aims at bringing relief by emptying the bladder in one way or another. When this is done, either by means of a catheter passed through the urethra and left in or through a suprapubic stab wound, the patient's condition, both general and local, improves rapidly. The uremic symptoms clear up, and the engorgement of the blood vessels of the prostate subsides, so that if the patient decides to postpone operation, he may remain free from obstruction for several weeks or months. Under ordinary circumstances surrounding a case of retention, drainage of the bladder thus forcibly established should be made through a suprapubic stab wound and considered a preliminary to the operation of prostatectomy, which is to be done when conditions warrant. During the period of preparation, it is advisable to keep the patient up and about. It is a well-known fact that old people do better when they are ambulatory and not infrequently the recognition and application of this knowledge rapidly promotes early and complete recovery. This applies to the period following operation as well as to that preceding operation. Prostatectomy patients should be encouraged to get out of bed as early as the fourth or fifth day.

Our earlier prostatectomies were done by the perineal route and with virtually no preliminary preparation of the patient. Although the mortality was not high, 6 per cent. for the class of

cases operated upon, the results were not all that could be desired. Healing of the wound was slow, and control uncertain. Then, we did much "fussing" with the patient after operation. Now the "fussing" is done before operation. This consists in the previously mentioned suprapubic drainage of the bladder, continued until the kidney function tested by the renal dye elimination is high enough to afford a good margin of safety, keeping the patient ambulatory, supplying the necessary diuretics, cathartics, and tonic treatment.

We do the operation by the suprapubic method, through a good-sized incision in the bladder wall. Except in the cancerous, the sclerotic and inflated forms of enlarged prostate, the operation is comparatively simple and invariably followed by the most happy results. The sclerotic and inflamed prostate is small, and presents real difficulties in its enucleation. It is almost impossible to obtain a plane of cleavage, and one feels that he must be satisfied with having removed the major portion of the gland without tearing into the cellular tissue. So with the enucleation of the cancerous prostate, the execution of which is fraught with considerable risk. Again one must be satisfied to get out what he can with safety and leave the rest for radium treatment, which now has a definite place in dealing with cancer of the prostate.

Death occurring within the first forty-eight hours after operation is frequently the result of shock, which is usually induced by inordinate bleeding. Squire's (*loc. cit.*) analysis of seven deaths occurring in 100 prostatectomies gives shock as the cause in three, anuria in two, and pulmonary embolus in two. Before the two-stage operation was established, Tenney and Chase (*Boston Med. and Surg. Journal*, Mar. 25, 1915) showed that 41 per cent. of the postoperative mortality was due to either uremia or sepsis. Modern methods have practically eliminated the deaths from these causes. During prostatectomy, a moderate amount of bleeding is expected and allowed to progress without the employment of the common measures for hemostasis. It usually stops spontaneously but not always. If blood pressure rises upon return of consciousness, bleeding may increase. The volume of blood and its coagulability varies considerably in different individuals, and the manifestations of excessive blood loss are not always typical. Therefore, it is often difficult to recognize the approach or actual crossing of the danger zone. This complication should not add more to the risk of the suprapubic operation because the operative field is in plain view and the operation should not end until hemostasis is evident. Bleeding may be controlled by gauze packing, the inflation of a rubber bag in the prostatic pouch, or suturing the pouch over with catgut. The latter method is the one which we have employed. The only safe course is to leave the operating table with a feeling of assurance that bleeding is controlled.

We believe that the risk of operation is greatly increased if it is performed too soon after the patient enters the hospital. In spite of an occasional high percentage of dye elimination during the renal function test, these patients generally are poor risks. They postpone operation until a condition of exhaustion from pain, loss of sleep, and toxemia causes pronounced irritability and impatience. Once decided upon operation, they become impatient about waiting and are apt to press the surgeon into immediate action. One of our patients, in complaining about the waiting period, stated that it caused him considerable worry and that his attitude was like that of Daniel Webster who was interrupted and delayed during a conference and exclaimed, "The best way to resume is to resume!" If an operation was in the foreground, he believed that the best way was to have it done as soon as possible, but in surgery of the prostate the best way to operate is not to proceed with the major effort at once. This patient gained time and perhaps life by the necessary preparation. The benefits from preliminary drainage of the bladder are not only constitutional but local. Those which take place locally loom large in the immediate outcome of operation by clearing up infection of the bladder mucosa, reducing the inflammatory changes around the neck of the bladder and by allowing the engorged blood vessels to regain their normal size and contractility. Add these items to greatly improved renal function and one can feel assured that the chances of success are greatly enhanced.

Finally, it may be said that with the exception of the rare and unfavorable forms of prostatic hypertrophy one is justified in making the assuring statement that few major operations in surgery involve less danger and are more instrumental in prolonging life and the joy of living than suprapubic prostatectomy intelligently approached and well done.

THE RELATIONSHIP OF PELVIC DISORDERS TO THOSE OF ADJACENT VISCERA.*

By JAMES W. NIXON, Jr., M.D.,
SAN ANTONIO, TEX.

THE subject that has been assigned to me for this evening's discussion is not only a broad one, but it has been so frequently discussed at meetings of this kind that there would seem to be little that is new to consider.

At the same time errors in differentiating between disease of the uterus and its adnexa and disease of the appendix, the rectum and neighboring organs are so frequently made and a correct preoperative diagnosis is of such vast importance that it seems worth while to consider briefly some of the more important points in diagnosis of the pathology associated with disease of the pelvic organs.

It is a well-known fact that the appendix is frequently involved in disease of the female pelvis. But in spite of extensive literature on the subject the exact incidence has not been recorded. In my limited experience, without committing myself to figures, I should estimate it so high as to make it a rule whenever called upon to do an appendectomy on a woman, never to omit examination of the pelvic organs. The importance of this was emphasized in a paper by Pozzi and Terrillon in 1890, and has been the method pursued by the best surgeons before and after that time.

The association of appendicitis and salpingitis

*Read before the Bexar County Medical Society, Jan. 27, 1921.

is familiar to every surgeon, but the sequence of cause and effect is not definitely settled; we merely know that the tubes may become involved through extension of infection from the appendix, and *vice versa*—a salpingitis may be the original cause of a subsequent appendicitis. Furthermore, the tubes and the appendix may be simultaneously involved by separate and distinct diseases. It is this fact that stresses the necessity of examining both these regions when called upon to operate for a lesion of one or the other. Neglect to do this may result in the embarrassing position of subjecting the patient to a second operation which could easily have been avoided.

Petersen in a series of two hundred cases found that the appendix was normal in only 50 per cent., and Gobritz found it normal in only 40 per cent., while Child in a study of 746 cases, covering all types of pathological conditions of the pelvic organs, found a diseased appendix in 244, or 32.5 per cent. of the entire series. On the other hand, the danger of the appendix becoming involved through disease primary in the tubes is apparent from the observation that 66.66 per cent. of cases of right salpingitis are complicated by appendicitis. (The incidence in left salpingitis is much lower.)

With regard to the incidence of appendicitis in the male and the female, there used to be a tendency to believe that owing to the liberal blood supply to the female pelvis, women enjoyed a certain immunity from disease of the appendix; but this apparent immunity is more than counterbalanced by the frequency of disease of the pelvic organs in the female, and the danger of appendicitis as shown by the figures just quoted. Most operators claim a larger incidence of appendicitis in the female than in the male, but in the experience of Deaver the disease seems to favor males. This, however, is one of those intricate matters of statistics that depend on so many circumstances that it is difficult to state the exact proportion without entering more deeply into the subject. It may be said in passing, however, that Deaver's comparative figures, 61.87 per cent. male, against 38.13 per cent. female, may be due to the fact that being a general abdominal surgeon he sees more male patients than female since the latter are more likely to consult the gynecologist; it is for this reason, also, that more of Deaver's appendectomies are done through a McBurney incision than through a straight one.

Although the appendix plays a leading rôle in the development of infection of the uterus, tubes, and ovaries, the rectum is often very obtrusive, to say the least. There are very few surgeons who have not been confronted with the trying situation presented by a rectum adherent to the pelvic organs. Only recently I had the opportunity of observing the trouble such pathology can produce. An infected ovarian cyst was so firmly adherent to the rectum that it was only with the utmost care and precaution that the adhesions could be separated without injuring the rectum. In another similar instance, the rectum was injured in separating an adherent pyosalpinx, and a fecal fistula resulted. In view of this and other unpleasant possibilities it is better in such circumstances to allow a portion of the indurated tissue to remain adherent to the rectum rather than to attempt to find a line of cleavage, with the risk of traumatizing the rectum, which, as we all know, is an organ to be treated with the utmost respect. Oftentimes it has proved to be a "boon" to both surgeon and patient. In cases of prolonged pelvic infection where, owing to the depleted condition of the patient, operation is inadvisable, recovery may take place through the liberation of pus having found an outlet by way of the rectum. In fact, sometimes hemorrhoids have been cured by hysterectomy, due to the relief of pressure on the rectum which had produced the hemorrhoids. I have observed two such cases. Oftentimes stricture of the rectum results from induration of its wall—the outcome of close association of the rectum with an infected pelvic organ.

The urinary symptoms developing from pressure of a fibroid, a cyst or a pelvic abscess are frequently the chief complaint. Spontaneous rupture into the bladder of a degenerated myoma uteri has been encountered and injury to the bladder or ureter, which has lost its normal anatomical relations by adhesions or tumors is neither a curiosity nor a pleasure to the surgeon. The close relation of the bladder to other pelvic organs is only too familiar to everyone.

The omentum, well named the "policeman" of the abdominal cavity, may also lead to unpleasantness. It always appears at the site of trouble, and it is often found plastered to a pelvic organ following some inflammation of the "arrested" viscus. In this position the adherent omentum, by restricting the normal intestinal fredom, may give rise to symptoms of intestinal obstruction. There are other pitfalls in this connection; for example, after an attack of acute gonorrheal salpingitis had subsided, a patient under my care developed a high temperature, a rigid abdomen, and a high leucocytosis. Examination of the pelvis failed to reveal any physical signs which might account for the symptoms. At operation a large omental abscess was found, the smear from which contained Gram-negative intracellular diplococci.

Although a small intestine may become involved in pelvic disorders, we are concerned, perhaps, less about its safety than about that of the large intestine. Adhesions and intestinal obstruction are the complications to be most feared in connection with this viscus. A fistula here from the abovementioned cause is rare; but when present it gives the surgeon more concern than does a fistula of the large bowel.

The opportunities for mistakes in diagnosis thus are numerous. The most frequent seat of error in the diagnosis of abdominal conditions in women is found in the right side of the abdomen. Inflammation of the tube, ectopic gestation, ovarian cyst, intraligamentary cyst, pyelitis, stricture of the ureter, or the passage of a calculus along its course have all been mistaken for appendicitis. And appendicitis, on the other hand, which is located deep down in the pelvis, has been diagnosed as acute salpingitis; even a pelvic abscess pointing in the posterior vaginal vault may be due to appendicitis. An ovarian cyst, we know, can easily be confused with myoma uteri.

The value of a correct diagnosis is undisputed. To get this, a complete, careful history is of pri-

mary importance. To my mind this stands far ahead of any other diagnostic means which we have at hand. Many of us have seen an ectopic gestation neglected because the physical signs and the laboratory findings were given precedence over a definite and clearcut history. Next in importance is the physical examination. Very often, in fact, owing to the low mentality of the patient, we are forced to rely completely on this means of arriving at a diagnosis. Wherever it is possible a complete blood examination or any other desired laboratory test should be employed to confirm the diagnosis, and thus make the condition reasonably sure. The character and the gravity of the surgical procedure and its result may depend, in large measure, on the diagnostic and manual skill of the surgeon. It is my belief that as a general rule for appendicitis in the female, although the diagnosis may be fairly certain, it is safer to adopt the so-called straight incision rather than the McBurney. The straight incision permits inspection of the pelvic organs which, as we have seen, are so often involved that routine examination is most desirable. This cannot be done through the small McBurney. It is, therefore, no exaggeration to state that the advantages of the McBurney over the straight incision are too few to risk the need of a second operation in doubtful lower abdominal conditions in women.

331 Moore Building.

A CASE OF EPIDEMIC MENINGITIS TREATED BY COMBINED SERUM AND VACCINE THERAPY.

By CHARLES E. NAMMACK, M.D.,

NEW YORK.

CAPTAIN, M. R. C., U. S. A.; ASSISTANT VISITING PHYSICIAN, BELLEVUE HOSPITAL; CLINICAL INSTRUCTOR IN MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

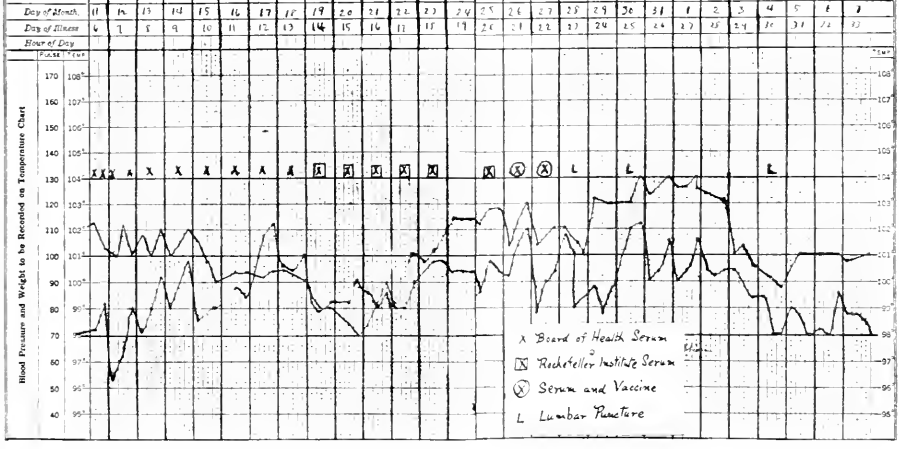
I WISH to present a case of meningococcus meningitis treated by serum and vaccine therapy. The following case has been considered worth bringing to your attention because, while it presents no strikingly unusual features, yet the problems which it presented and the methods used to combat them may prove of some value in similar cases.

The patient, a girl of eighteen, was admitted to the Fourth Medical Division of Bellevue Hospital, October 11, on Dr. Charles E. Nammack's service. The chief complaints were headache, vomiting, stiff neck, and fever. On examination she presented all the classical symptoms of meningitis. Five days before admission and one day before the onset of the severe symptoms she had complained of severe earache without any evidence of discharge from the ear. For this reason it was considered not unlikely that she was suffering from a secondary meningitis, probably pneumococcic. The ears and mastoid were negative, however, and there were no petechiæ found.

On admission the temperature was 102.4°, pulse 72, respirations 24, and the patient was markedly prostrated. Lumbar puncture was done and a large amount of turbid spinal fluid, under greatly increased pressure, was withdrawn and 30 c.c. of Department of Health antimeningogoccus serum was administered intraspinally by the gravity method. The analysis of the spinal fluid showed a tremendous increase in cells with 95 per cent. polys, globulin 4 plus, Fehlings negative, and numerous Gram negative intra- and extracellular diplococci, which proved to present the cultural characteristics of meningococci. The lumbar puncture was repeated in twelve hours with another injection of serum—20 c.c. this time.

The following day the patient was extremely restless, complaining bitterly of headache, and it was necessary to give her 6 minims of Majendie's solution and gr. 1/150 of atropine, both during the day and at night. In addition, two lumbar punctures were performed and she received 50 c.c. of serum intraspinally. The patient received daily treatments on the four succeeding days and on the 16th the temperature began to go down, there was considerable improvement in her symptoms, and a diffuse urticarial rash of serum sickness appeared. Lumbar punctures done on the seventeenth and eighteenth days showed the fluid to be still extremely turbid, however, and meningococci were present in both smear and culture. It was then found that the Department of Health serum which was being used did not agglutinate the strain of meningococcus isolated from this case. Although the efficiency of a serum does not depend entirely upon its agglutinating powers, it was considered best to employ another serum and some serum was obtained from the hospital of the Rockefeller Institute.

Daily doses of this were given from the 19th to the 23d of October and also on the 25th; the fluid continued turbid and organisms were still present, although less numerous, and the temperature reached normal on the twentieth day, but again rose. It was found that the



Rockefeller serum also failed to agglutinate the organism of this case. In the meanwhile an autogenous vaccine had been prepared and on October 26 30 c.c. of cloudy fluid was removed and the patient received 20 c.c. of Department of Health serum with one-half c.c. of vaccine, the strength of which was one billion organisms per c.c. The fluid the following day showed only a slight turbidity and the dose of vaccine and serum was repeated and was followed two hours later by a severe chill lasting about ten minutes and a rise of temperature to 102°. Lumbar punctures were done on the 28th and 30th, and November 4, but no serum or vaccine was given, as the fluids were clear and sterile and there was a steady decline of the temperature to normal. Convalescence was slow but uneventful; there were no sequelæ, and the patient was discharged to go to the country to recuperate on December 1, 1920.

The interesting features of this case are: (1) Failure to respond to serum treatment intraspinally given intensively but with a serum that failed to agglutinate the organism present. (2) The continuance of the symptoms and the presence of organisms in the spinal fluid under further lumbar punctures and serum therapy. (3) The prompt response and improvement going on to complete recovery following the employment of mixed serum and autogenous vaccine treatment intraspinally. I am not prepared to say what the rationale of this treatment is but I believe that it is a specific response in the production of antibodies due to the introduction of foreign protein similar in effect to that produced by the use of typhoid vaccine in cases of arthritis, differing, however, in being specific because treated by a vaccine made from the particular organism present in the spinal fluid. During the past year we had in the Meningitis Division of the Department of Health two cases cured in which autogenous vaccine was employed intraspinally. One of these cases was influenzal meningitis and the other staphylococcic, detailed accounts of which will appear elsewhere in the near future. This form of therapy may offer hope in cases of purulent meningitis which are regarded as uniformly fatal.

In connection with the case that I have described there were two things that might well have done at the outset. One would have been to test the serum to be used as to agglutinating power before beginning its use, but when one is using a polyvalent serum this is not usually considered necessary. Again, we might have given serum intravenously following the plan of combined intraspinal and intravenous therapy employed with such success by Dr. W. W. Herrick at Camp Jackson during the epidemic there among the troops. Dr. Josephine B. Neal and others do not consider it advisable to use serum intravenously unless there are evidences of a meningococcus bacteriemia; there was no such evidence in this case although a blood culture was not taken. Attached is the temperature chart from admission until the temperature reached and remained normal.

In regard to the administration of vaccine intraspinally, I would like to say that had we not been using a specific serum as in this case, we would have diluted the vaccine with an equal amount of sterile saline solution. In a case of influenzal meningitis treated by me by this method, combined with subcutaneous injections, an infant three months old lived three weeks with marked improvement in symptoms and finally succumbed apparently because of a complicating bronchopneumonia.

Medicolegal Notes.

Abrasion Permitting Erysipelas Germs to Enter—Question of Voluntary Exposure for Jury.—In an action on an accident policy over the life of a physician it appeared that the insured accidentally caused a scratch or abrasion of the skin of the ear in adjusting his glasses while attending a patient suffering from erysipelas, and germs entered the wound and caused infection. The Georgia Supreme Court holds that it was a question for the jury whether recovery should be denied on the ground that the infection occurred from the insured's voluntary act in subjecting the wound to exposure; and judgment for the defendant was reversed.—Bell v. State Life Ins. Co. of Indianapolis (Ga.), 105 S. E. 846.

Administration of Anesthetics—Burden of Proof of Negligence on Plaintiff in Malpractice Case.—In an action for malpractice it appeared that the defendant caused an anesthetic to be administered to a patient, preparatory to performing a surgical operation. The patient died from the effects of the anesthetic before the operation was commenced. The action was for damages for the death. The lower court granted a nonsuit, from which the plaintiffs appealed. They charged negligence in causing the anesthetic to be administered at the particular time, when the patient was in an unfit condition. The evidence showed that the operation, which was for a comminuted fracture of both bones of the right forearm, had been from time to time delayed over a period of two or three weeks, solely on account of the patient's intemperance. Finally, "he appeared at the hospital 'more sober than he had been, but he showed the effects of drinking,' and, accepting the advice of Dr. Scott, stayed there overnight, during which time the doctor got him in as good condition as he could under the circumstances." The Montana Supreme Court said: "The consensual transaction from which arises the relation of physician and patient does not imply absolute liability. A physician is not an insurer, and a malpractice case does not differ in its essential ingredients from any other action for damages arising from negligence. The law does not presuppose that for every injury there must be a recovery in damages. The gist of this action is negligence, and actionable negligence arises only from a breach of legal duty.—Jonosky v. Northern Pac. Ry. Co., 57 Mont. 63, 187 Pac. 1014. What, then, was the legal duty Dr. Scott owed to Charles Lowden? The standard of legal duty owed by the physician the court stated to be the exercise of such reasonable care and skill as is usually exercised by physicians or surgeons of good standing of the same system or school of practice in the community in which he resides, having due regard to the condition of medical or surgical science at that time.

"There was no expert testimony in the case that the defendant's action in causing the anesthetic to be administered indicated the exercise of want of ordinary care, skill, or diligence as required in malpractice cases in that jurisdiction and elsewhere generally."—Stevenson v. Gelsthorpe, 10 Mont. 563; Witthaus & Becker on Medical Jurisprudence, 87. No presumption of negligence arose from the fact that it was dangerous then to administer the anesthetic, the evidence showing that the element of danger is present in every instance where a patient is anesthetized. "The gravamen of this case is negligence, and negligence cannot be inferred from the fact alone that the patient died. Haire v. Reese, 7 Phila. (Pa.) 138; Bonnet v. Foote, 47 Colo. 282; 107 Pac. 252, 28 L. R. A. (N. S.) 136. The maxim, '*Res ipsa loquitur*,' has no application to a case of this character. Ewing v. Goode (C. C.), 78 Fed. 442. Negligence is not to be presumed; it must be proved (Reino v. Montana M. L. Co., 38 Mont. 291, 99 Pac. 853), and plaintiffs were required to assume the burden of proving the negligence charged and that Lowden's death resulted proximately from such negligence (3 Wharton & Stillé's Medical Jurisprudence, § 500). From the very nature of the case, each of these ultimate facts required for its proof the testimony of one qualified to give an expert opinion (Pettigrew v. Lewis, 46 Kan. 78, 26 Pac. 452), and in the absence of such testimony the case failed." Judgment of nonsuit was affirmed.—Lowden v. Scott (Mont.), 194 Pac. 488.

TUBERCULOSIS IN NURSLINGS.

TUBERCULOSIS is frequent in nurslings, its frequency increasing with the age of the infant. Both sexes are equally attacked during the first year of life, but during the second, males suffer much more than females, the ratio being 5 to 2. In nearly 50 per cent. of the cases there is a history of tuberculosis in the parents. Familial contagion is of the highest importance, hence illegitimate babies are less often afflicted. When a nursing mother presents open tuberculous lesions the baby runs great risk of being contaminated. Two facts dominate the history of tuberculosis in nurslings. The first is that tuberculosis of the bronchial lymphnodes is almost invariably the first important focus of bacillary infection; it is the most constant localization and is found in most cases. This leads one to suppose that the usual entrance of the bacillus in nurslings is the respiratory tract, and it is exceptional to discover lesions which would indicate an intestinal origin of the infection. The second fact is that tuberculosis in early life tends to diffusion and this tendency is all the more marked the younger the child.

The respiratory forms vary. The tracheobronchial adenopathy, which is nearly always present, may be latent and merely cause pyrexia. Or it may give rise to physical signs or compression symptoms and occasionally to laryngeal phenomena. Bronchitis with a subfebrile state is frequent during the first year of life, offering a very commonplace aspect, but the general health of the baby and tuberculosis reactions will indicate its true nature. The infant may recover, but if he dies autopsy will reveal an ordinary bronchitis kept up by adenopathy, or an ulcerating pulmonary tuberculosis, unsuspected during life, may be found. Bronchopneumonia, frequent during the second year of life, has a bad prognosis. Sometimes localized in foci, at other times diffuse, it is usually characterized by the persistency of its symptoms and the profound changes in the general health. At autopsy, the usual lesions of bronchopneumonia, with or without distinct lesions of tuberculosis, will be found. Ulcerating pulmonary tuberculosis is difficult to diagnose in nurslings; even cavities often remain latent, but when hemoptysis occurs, which is very uncommon, it is a sure symptom of this process. Pleural manifestations are rare and consist of a purulent collection due to the ordinary forms of infection. The dry forms are found only at necropsy.

The digestive manifestations may be divided into simple dyspepsia and gastroenteritis. The former is observed especially during the first year of life and is characterized by emaciation and hyperthermy which are disproportionate to the intensity of the digestive symptoms, the latter being in reality mild. Death often occurs in one to three months. Gastroenteritis, which is quite as frequent during the second as during the first year of life, offers the ordinary clinical aspect of this affection, but its characteristic is that no improvement occurs in spite of a perfectly regulated diet. The nature of these processes is often obscure, and as they cannot be attributed to tuberculous changes in the digestive tract, it is probable that their causal factor resides in tuberculous intoxication.

External tuberculous manifestations are not very uncommon in nurslings, particularly osteitis, Pott's disease, spina ventosa, orchitis, subcutaneous gummata, and, more rarely, tuberculides.

The most frequent nervous manifestation of tuberculosis in nurslings is meningitis, while its forms are rather remote from the classified type met with in older children. The eclamptic and somnolent forms are common, likewise the form with paralytic localizations.

Generalized tuberculosis in nurslings often assumes the form of chronic miliary tuberculosis with tubercles scattered throughout the thoracic and abdominal viscera. Clinically, it is made evident by atrophic cachexia with apyrexia, polyadenopathy, and enlarged spleen and liver. Generalized tuberculosis may assume an acute course, either the asphyxiating or the typhoid forms.

In all these various tuberculous processes in nurslings, autopsy usually reveals far more extensive and advanced lesions than were suspected during life, and reactions toward healing are rarely found. Like all chronic infectious processes tuberculosis may act on the bone marrow and cartilages of ossification, thus producing rickets, and the latter condition during the second year of life has been shown by Marfan and Mantoux to depend frequently upon tuberculosis. The diagnosis of tuberculosis in nurslings depends essentially upon tuberculin reaction, and the cutireaction should be the clinician's guide. A positive result will often clear up the nature of symptoms of what was thought to be an ordinary affection of the first two years of life.

EARLY DIAGNOSIS OF CANCER OF THE UTERUS.

THIS subject is a trite one, yet one of great importance and one that can hardly be discussed too often. Many accomplished and conscientious practitioners are not honest with themselves when they suspect the existence of a beginning cancer of the

cervix and hesitate to submit their patients to a hysterectomy which might possibly turn out to have been unnecessary. These physicians wish their diagnosis to be absolutely certain before they countenance this ordeal. They also shrink from terrorizing the women, although to-day the problem has been simplified because the mortality of vaginal extirpation is small—and there is also radium. But to minimize the unpleasant features, it is necessary for the disease to be detected at the earliest moment, and there should be no difficulty in diagnosis if we are circumspect. Sireday, writing on this topic in the *Journal de Médecine et de Chirurgie Pratiques*, xci, 22, says there are three elements which tend to cloud the diagnosis and we have to bear these carefully in mind. First is the age of the subject, for we are most apt to think of cancer at the age period 40-50. This is the rule, but the disease may occur at almost any age and the author has had in his hospital service at one time as many as four or five cases of cervical cancer in women under 35. In his consultations he sees the disease at 28, 26 and 25, and recently he saw a woman of 24, two months pregnant, with cancer of the cervix. He has very exceptionally seen the disease at 23 and 22, while the record in his experience was in a girl of 19, although he has seen a cancer of the rectum in a girl of 18.

The second deceptive factor is the apparent good health of many of the victims. In fact, it is only at an advanced period that the general appearance is altered. Some of the women may be in bad health, thin and anemic, but not from the cancer. On the other hand many seem in magnificent health and vigor—shopkeepers of opulent proportions such as delicatessen store proprietresses, wine dealers, and costermongers with red, outdoor complexions, or corpulent women of the world. Some of these women weigh as much as 220 pounds. Health and youth should not therefore mislead us. Another source of confusion attaches to the menopause with special reference to hemorrhages. It is taught erroneously that a woman should bleed at this period, but this is true only of a certain percentage in whom there is at this time of life a true menorrhagia. This may preserve much regularity but even when irregular and atypical the woman goes a number of days in succession without any loss of blood; in cancer this negative behavior would not be in evidence. In these cases moreover there is a strong presumption of fibroid uterus and examination may confirm this presumption. In other cases we think of angiosclerosis in which condition the uterus may be enlarged or normal in size. We do not know much of the intimate nature of this condition, but as in the case of fibroid uterus the hemorrhage is a menorrhagia, not a metrorrhagia. In rare cases only, a small, detached fibroid in the cavum uteri has been known to cause continuous hemorrhage. But any diagnosis whatever of fibroids should not blind us to the possibility that cancer may coexist. Fibroids are believed to cease growing after the menopause; when after a period of quiescence they appear to grow anew the chances are that sarcoma has begun. When a true metrorrhagia starts up after a period of post-climacteric amenorrhea it is almost certain evidence of cancer; in the rare exceptions a myoma has undergone necrosis. Vaginal examination may reveal nothing at all to the eye or finger, although careful palpation may reveal a slight irregularity in form or consistency with a tendency to bleed on scratching with the finger nail.

The author has the temerity to advocate a biopsy and even to say that it must be repeated once or twice in case the first findings are negative. If later the poor woman died, as she probably would, the surgeon, if a devout man, would probably regard it as the will of God, and not as murder, his only regret being that the biopsy was not made early enough.

In practice one should always assume that the focus is larger than it seems, especially in young women in which the affection travels rapidly. In 15 or 20 days a socalled operable case may become inoperable.

THE PATHOLOGICAL DIAGNOSIS OF SINUSES IN THE NECK.

THE lesions giving rise to sinuses in the neck are many, therefore the subject of differential diagnosis is important. Congenital fistulæ are usually seated in the supra or infrahyoid regions, their external opening being in proximity to the anterior border of the sternomastoid muscle. They are usually incomplete and the probe will strike against the hyoid bone. Their direction is generally from above downward and forward. When complete they open into the larynx in most cases. The fluid secreted is serous, small in amount and contains epithelial débris. Dermoid cysts of the tongue or neck are due to an inclusion of a fold of the ectoderm between the two halves of Meckel's cartilage and since this cartilage precedes the appearance of the jaw it results that cysts of the tongue are behind the symphysis. Dermoids are met with at any point on the median plane of the neck, from the floor of the mouth to the sternum, even in the mediastinum, along the internal border of the sternomastoid. The diagnosis of a sinus arising from these dermoids is often difficult.

In cervicofacial actinomycosis the evolution is slow, the process sometimes remaining stationary. The skin is wine-red or violet, tumefied, and this tumefaction may involve the entire side of the face or neck. The edges of the sinuses are undermined and granulating, but enlarged lymph-nodes of any size are wanting. The pain will be seated at the angle of the jaw. Suppuration is slight and the pus obtained by pressure is grayish-yellow, clotted, and occasionally bloody. Trismus occurs early in the process and indicates inflammation of the muscles. Microscopical examination of the secretion will reveal the actinomyces.

The etiology of salivary sinuses will make their diagnosis easy; a former trauma has caused either Wharton's or Stenson's duct to communicate ex-

ternally. The discharge is saliva, never pus, and flows off especially at meal time. Sinuses from tuberculous adenitis need not be described, as such lesions are common, but those arising from syphilitic osteitis of the lower jaw are important and need description. These bone lesions may appear during the secondary phase of the infection, but more commonly occur during the third phase. They are usually seated at the angle of the jaw. Their characteristic sign is noctural osteocopic pain but occasionally they may be indolent until they set up a neuritis from compression of a nerve. Exquisite pain is produced by palpation. The skin surrounding the sinus is red-violet in color, the edges of the ulcer are round, undermined and pus makes its exit only at the latter part of the evolution of the process; the discharge is at first serous and contains caseous lumps.

Fistulous abscesses and phlegmons of the neck are almost always due to infection of the lymph-nodes. Adeno-odontopathic sinuses are dental in origin. The former process occurs after diphtheria, scarlatina, or measles, also after rhinitis or otitis. Sinuses resulting from osteomyelitis of the jaw are in most cases primarily due to a periodontitis, occasionally a periadenitis, the necrosis in the jaw being secondary. The evolution of the process takes place in a few days. Pain is severe with high fever and a painful tumefaction of the entire region exists. Pus escapes by the sinuses opening on the cutaneous surface and by the alveoli. Sinuses due to phosphorus necrosis of the jaw will be readily diagnosed from the history of the case. They give issue to very fetid pus, while severe salivation, reaching to two to four quarts a day may be present.

Lenticulo-Striate Syndromes.

This was the subject of a recent clinical lecture by Sainton, reported in *Le Progrès Médical* for April 30, 1921, xlix., 18. After a brief enumeration of the nerve centers involved, the author sketched the so-called Wilson's disease, otherwise known as juvenile degeneration of the lenticular nucleus. The tremor in this affection has a striking analogy with that of Parkinson's disease, while the hypertonus is absolutely comparable with that of the same affection. In several other respects and in the incidence of Wilson's disease in young subjects, the two maladies show notable departures. In Wilson's disease there are progressive psychic troubles, but unlike psychoses in which the cortex cerebri is involved, the reflexes are normal or in other words the pyramidal system is not compromised. For the same reason sensory disturbances are absent. The picture is essentially a motor one—tremor, rigidity, and muscular asthenia. In the elderly subject who has had a cerebral hemorrhage we may at times see a similar picture. Either the hemorrhage itself or the secondary softening has occurred in the pallidal or pallidostriate region. There are a mask-like expression, tremor of the hands, and a hesitating, somewhat ataxic gait. The symptoms present suggest the spastic paralysis of Little's disease; there are general rigidity, choreiform or athetotic movements, and pseudobulbar symptoms. The lesion involves the striate area but spares the pallidal region. The lecturer showed a patient with this affection side by side with a case of Huntington's chorea. He would also place the latter affection among the striate syndromes. In describing the pallidal syndrome the author draws freely on the account of "Ramsay," who is of course Dr. Ramsay Hunt of New York, whose name is closely identified with this syndrome. It is of interest to note that a pallidal syndrome is often seen in encephalitis lethargica—the so-called pseudo-Parkinson picture of that disease. The pallidostriate area is closely connected with the thalamic areas—red nucleus, locus niger, and Luys's body; so that in lethargic encephalitis both systems are involved. In the author's opinion the pallidus exerts a motor-inhibitory action, while the striate nuclei are coordinating exciters of motor functions.

Cancer of the Matrix of the Nail.

This affection must be one of the rarest known. In the large monograph by Heller on diseases of the nails which appeared in 1900, but three cases seem to have been reported. A new one has recently been placed on record by Dr. Carlos Chagas of the faculty of the medical college of Bello Horizonte, in an article in the *Brazil-Medico* for May 7, 1921, xxxv, 19. This is not the first appearance of the patient in medical literature, for the case was reported in the *Archivos Mineiros de Dermato-Syphiligraphia* for November 19, 1919, with the title "A Case for Diagnosis." The patient is a man of 60 at the present time, a laborer. There was a history of traumatism involving the right great toe, but as this had occurred 20 years before it could not be brought in any causal relation with the cancerous growth which dated back a year and 6 months and began with a simple thickening of the nail of the toe in question. The condition appeared to have been one of onychauxis suggesting a cutaneous horn, but preserving throughout the semblance of a nail. It was at this juncture that Drs. Aleixo and Orsini of the Clinic for Dermatology and Syphilis showed the case to the profession and reported it as above stated. The possibility of an epithelioma had been incidentally canvassed. Dr. Chagas then made a biopsy of a fragment of the hypertrophic nail and the latter was seen to be an exquisitely keratinized epithelioma. The type of tumor was therefore of the rarest—if possible more nearly unique than the location of epithelioma of the nail. Chagas can find no record of such a tumor in literature and the cases quoted by Heller are all of a different type. The toe was amputated and the man, apparently cured, disappeared. The diagnosis was confirmed by a histological study of the specimen.

News of the Week.

Additional Hospitals for Soldiers' Homes.—Secretary Mellon has approved an allotment of $3,100,000 out of the special hospitalization fund of $18,600,000 to the Board of Managers of the National Homes for Disabled Volunteer Soldiers, to be expended in the development and expansion of existing national soldiers' homes into hospitals for

the treatment of veterans of the World War afflicted with tuberculosis. The project includes the national homes for disabled volunteer soldiers at Milwaukee, Wis.; Dayton, Ohio; Leavenworth, Kas.; the Battle Mountain Sanitarium at Hot Springs, South Dakota, and the Marion National Sanitarium at Marion, Ind. These institutions will be used for cases of tuberculosis and of nervous and mental disease which require a long time for rehabilitation.

Chemists Fear New Dry Bans.—The counsel for the National Wholesale Druggists' Association, W. L. Crounse, before a recent meeting at the Chemical Club in New York City declared that the Volstead amendments would stop the manufacture of necessary medicines. He alleges that alcohol is being denied to reputable pharmaceutical manufacturers and wholesale druggists and, at the same time, permits have been issued to 4,000 persons not on record as users of alcohol before prohibition, and who are now employing it as a basis for bootleg whiskey. Mr. Crounse asserts that many reputable manufacturers have had their alcohol supplies cut off for from two to six weeks by some subordinate in the bureau who decided that these firms were using more alcohol than he deemed necessary. Their requisitions have been denied despite the fact that they never have exceeded the permits and bonds of the houses in question. He says there are 3,600 medicinal preparations manufactured in the United States in which alcohol is a necessary ingredient.

Jewish Organization on Lines of Red Cross.—A special cablegram from Geneva to the *New York Times* announces the founding on June 23 of the Red Shield of David, a Jewish organization which will be managed on the same lines as the Red Cross, and which intends to work hand in hand with the League of Red Cross Societies and the Red Crescent. Several leading Jewish physicians, merchants, and philanthropists are at the head of the movement.

State Accused of Profiteering in Hospital.—The American Legion's investigating committee on insane and other mentally afflicted ex-service men now confined in the Manhattan State Hospital on Wards Island has requested the United States Senate and the authorities of New York State to conduct an inquiry with the object of putting an end to the alleged profiteering by the State through this institution. The committee is said to have found 200 ex-service men on Wards Island mixed in with permanently insane and hardened cases under conditions which make it practically impossible to give them any special treatment. The committee alleges that the State is paying only 90 cents a day per man, although the United States Government is paying the State $2 a day for each government inmate. The committee urges the erection of the proposed Creedmoor Hospital on Long Island.

Wins Damages for Diabetes.—A jury before the Supreme Court in Brooklyn recently upheld the claim of Mrs. Rose Cohen, that as the result of a collision between a truck of the Bacon Coal Company and a Gates Avenue car in Brooklyn, in 1919, she was injured in such a manner that diabetes developed and she became an invalid and lost seventy pounds. The jury gave a verdict of $12,000 against the coal company. During the trial Sir William Osler was quoted to prove that diabetes could be caused by shock.

Drive for Volunteer Hospital.—General Ballington Booth announces that he will begin a drive in September to raise $500,000 for the Volunteer Hospital. William G. McAdoo will act as advisory chairman of the drive.

Antityphoid Vaccination for Vacationists.—The New York City Department of Health calls attention to the danger of exposure to typhoid fever during the vacation season and urges physicians throughout the city to persuade their patients to submit to immunization against typhoid before starting on their vacations. The vaccine may be obtained, free of charge, at the Department of Health for use by physicians, or the Department will immunize any individual, free of charge, at any of its clinics.

Sir **Robert Jones** of London, England, was awarded the honorary degree of Doctor of Science by Harvard University at its commencement on June 23.

Dr. Alexis Carrel has been elected a national associate of the French Academy of Medicine. Under the rules of the academy there may be only twenty national associates, all of whom have heretofore been residents of France.

Lieutenant General Dr. Otto von Schjerning, former Surgeon General of the German Army, died in Berlin on June 29.

Dr. Juan Fernando of the Philippine Public Health Service, has spent the last six months in making an intensive study of the methods used in the New York State Department of Health.

Dr. Malcolm F. Lent has tendered his resignation as Director of the Division of Tuberculosis of the New York State Department of Health, to take effect July 1. He intends to practise his specialty at Saranac Lake, N. Y.

Dr. J. M. Fernandez has been appointed assistant professor of ophthalmology in the University of Havana.

Gift to New York University.—The Rockefeller Foundation has contributed $35,000 to New York University to increase facilities for teaching preventive medicine and sanitation at the University and Bellevue Hospital Medical College.

Charitable Bequests.—Among the many recipients of bequests under the will of the late Mrs. Elizabeth Milbank Anderson are the following: The Children's Aid Society and the National Committee for Mental Hygiene, each $100,000; the Association for Improving the Condition of the Poor, New York, $200,000; Henry Street Settlement and the New York Hospital, $50,000 each; The Adirondack Cottage Sanitarium and the State Charities Aid Society, each $25,000.

Industrial Research Laboratories.—In the forthcoming revision of the *Bulletin of the National Research Council,* Number 2, research laboratories in industrial establishments of America are to be described. Only 300 such laboratories were listed in the first edition, but it is hoped that several new names will appear in the revision and that a more nearly complete reference list will become available. The Council requests information from directors of

research who have not already supplied it. The following data are wanted: Name and address of the firm and address of laboratory; name of director of research; number of laboratory staff (classified as chemists, engineers, bacteriologists, etc.); approximate proportion of time spent on research; chief lines of research; unusual features of equipment; research laboratory space; date of organization of research laboratory and annual expenditure for research. Confidential information is not desired. These data should be furnished as promptly as possible to the Research Information Service, National Research Council, 1701 Massachusetts Avenue, Washington, D. C.

New Quarantine Chief in the Port of New York.—Surgeon Samuel B. Grubb of the United States Public Health Service has been detailed as Chief Quarantine Officer of New York, succeeding Surgeon Leland E. Cofer, who has been relieved on account of ill health. Dr. Grubb is a graduate of the College of Physicians and Surgeons of Columbia University. He entered the Public Health Service on May 17, 1897.

A Bust of Morton for the Hall of Fame.—Acting on the suggestion of Dr. S. A. Knopf, the Associated Anesthetists, composed of seven different societies of anesthetists, have started a movement to place a bust of Dr. William T. G. Morton in the Hall of Fame on October 16, the seventy-fifth anniversary of the first public demonstration of ether anesthesia. Subscriptions may be sent to Dr. F. H. McMechan, Lake Shore Road, Avon Lake, Ohio.

Cape Town Swept by Influenza.—Influenza is sweeping through the Eastern Provinces of South Africa and many thousands of persons are reported to have fallen victims to the disease. The disease is most virulent in the town of Ultenhage, twenty miles northwest of Elizabeth.

International Fight on Cancer Planned.—The first direct result of America's radium gift to Madame Curie is the decision by the Franco-Anglo-American League for Prevention of Cancer, following conferences with M. Regaud, director of the biological laboratory at the University of Paris Radium Institute, to initiate a great international educational campaign. All Paris will be placarded with instructive posters in terms that can be understood by all telling how to recognize the first symptoms of cancer and advising sufferers to submit immediately to an examination by experts. The Radium Institute will develop a special free clinical service to carry out the league's idea and is relying on the American radium to provide the treatment.

Druggists Charge Law Discrimination.—At their annual meeting in San Antonio, June 17, the members of the Texas Pharmaceutical Association, by a rising vote, pledged their support to the National Association of Retail Druggists in the fight to be launched in the near future against alleged discrimination shown to retail druggists in the enforcement of the national prohibition act. The druggists are protesting because they have the greatest difficulty in securing permits to withdraw alcoholic liquors from government warehouses for legitimate medicinal purposes, while manufacturing concerns are given a free hand in withdrawal permits, in spite of the fact that it is generally known that the "medicine" they manufacture is to be sold as a beverage.

Physicians' Office Building.—The Herter residence on the southeast corner of Madison Avenue and Seventieth Street, New York, has been purchased for $200,000 for the site of a building to contain only offices for physicians and surgeons.

The American Electrotherapeutic Association will hold its Thirty-first Annual Meeting in Washington Hotel, Washington, D. C., Sept. 7th to 19th. Dr. Byron S. Price is President; Dr. A. Bern Hirsh, Secretary. This year, the meeting in addition to the scientific program will give two hours daily, to the practical demonstrations of how to use equipment to secure certain definite therapeutic results. Among those who will give demonstrations are Dr. Frederick de Kraft, general diathermy; Dr. Edward C. Titus, cerebral diathermy and the use of vacuum tubes with static current; Dr. Frank B. Granger, galvanic and sinusoidal current; Dr. Wm. Benham Snow, static current in the treatment of arthritis; Dr. Mary Arnold Snow, mechanotherapy, in the treatment of abnormal blood pressure; Dr. Howard T. Plank, active rays in the treatment of malignancy; Dr. Frederick H. Morse, the alternating currents. For scientific program, address Dr. A. Bern Hirsh, 71 W. 94th St., New York City; for details as to hotel accommodation, exhibits, entertainment for the ladies, address Dr. Elnora C. Folkmar, 1730 Eye Street, N. W., who is chairman of the Washington committee.

Medical Veterans of the World's War of the Missouri Valley and the Southwest will hold a joint session in Kansas City, October 25 to 28, 1921. A four day meeting is planned with clinics in the hospitals in the mornings and scientific sessions at which papers will be read in the afternoons. Five sections will hold sessions, comprising medicine, surgery, obstetrics, eye and ear, and genito-urinary. On October 24, the "Mid-Western Association of Anesthetists" will be organized and present a program. Communications may be addressed to Dr. F. H. Clark, Secretary of the Southwestern Association, Oklahoma City, Okla.

Tuberculous Children Sleep in Parks.—Tuberculous children from Westminster council schools have a class in St. James Park, London. In this class both health and education are considered. All the lessons take place in the open air, milk is provided for the children, and an hour's sleep is part of the daily routine. This siesta is taken in a sleeping bag on the park lawn, and serves not only to provide a beneficial rest but prevents the children from coming in contact with other children.

Drive for American Hospital in Paris.—A campaign is in progress in Paris to raise a fund of 5,000,000 francs to be used to increase the number of beds in the American Hospital in Paris from thirty to one hundred. Subscriptions on the first day amounted to 75,000 francs. Mrs. W. K. Vanderbilt gave the first subscription of 60,000 francs. It is the intention of the hospital directors to set aside one-third of the beds and make them available to any American who is unable to pay for hospital treatment.

Medical Society Elections.—THE CONNECTICUT

STATE MEDICAL SOCIETY, at its one hundred and twenty-ninth annual meeting, held in Hartford, May 19-21, 1921, elected the following officers for the ensuing year: *President*, Dr. Charles C. Godfrey, Bridgeport; *Vice-Presidents*, Dr. Leone F. LaPierre, Norwich, and Frederick P. Braden, Essex; *Secretary*, Dr. Charles W. Comfort, Jr., New Haven; *Treasurer*, Dr. Phineas H. Ingalls, Hartford.

THE HOWARD COUNTY (MO.) MEDICAL SOCIETY, at its annual meeting held in Fayette, May 15, elected the following officers for the ensuing year: *President*, Dr. W. M. Dickerson, Armstrong; *Vice-President*, Dr. W. E. Williams, Fayette; *Secretary-Treasurer*, Dr. R. H. Williams, Fayette.

THE BUFFALO (N. Y.) MEDICAL AND SURGICAL LEAGUE, at its annual meeting held May 18, 1921, elected the following officers: *President*, Dr. Frank Kleckner; *Vice-President*, Dr. Edmund P. Reimann; *Treasurer*, Dr. George C. Clark; *Secretary*, Dr. Charles Bethune.

THE OKLAHOMA ECLECTIC MEDICAL ASSOCIATION, at its annual meeting held in Oklahoma City, May 18, 1921, elected the following officers for the ensuing year: *President*, Dr. L. H. Henle, Claremore; *First Vice-President*, Dr. P. L. Neblitt, Erick; *Second Vice-President*, Dr. G. S. Petitt, Oklahoma City; *Third Vice-President*, Dr. E. G. Massinglee, Sapulpa; *Secretary*, Dr. T. C. Leachman, Woodward; *Treasurer*, Dr. William King, Oklahoma City.

THE STATE AND PROVINCIAL HEALTH AUTHORITIES OF NORTH AMERICA, at their annual meeting held in Boston, June 2, 1921, elected the following officers for the ensuing year: *President*, Dr. Eugene R. Kelley, Boston; *Vice-President*, Dr. Oscar Dowling, New Orleans, La.; *Secretary-Treasurer*, Dr. R. M. Olin, Lansing, Mich.

THE SCHUYLER COUNTY MEDICAL SOCIETY, at an adjourned annual meeting held in Watkins, June 2, 1921, elected the following officers for the ensuing year: *President*, Dr. Albert Warren Ferris, Glen Springs; *Vice-President*, Dr. R. M. Clark; *Secretary*, Dr. R. C. Baker; *Treasurer*, Dr. D. M. Scutt.

THE ALUMNI ASSOCIATION OF THE COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY, at its annual meeting held at the university, June 11, 1921, elected the following officers for the ensuing year: *President*, Dr. Herman G. Weiskotten; *Vice-President*, Dr. W. D. Johnson, Batavia; *Secretary*, Dr. Carlton F. Potter, Syracuse; *Treasurer*, Dr. Albert G. Swift, Syracuse.

THE NATIONAL TUBERCULOSIS ASSOCIATION, at its annual meeting held at the Waldorf-Astoria, New York, June 15-17, 1921, elected the following officers for the ensuing year: *President*, Dr. James Alexander Miller, New York; *Secretary*, Dr. George M. Kober, Washington, D. C.; *Treasurer*, Henry B. Platt, New York.

THE CONNECTICUT HOSPITAL ASSOCIATION, at its second annual meeting held in Meriden, June 1, 1921, elected the following officers for the ensuing year: *President*, Dr. Harold W. Hersey; *Vice-President*, F. L. Hutchins, Norwich; and Sister Alice, Superintendent of St. Vincent's Hospital, Bridgeport; *Secretary*, Miss Alice Hunter, Superintendent Grace Hospital, New Haven.

Obituary Notes.—Dr. WALTER BERNARD WINCHELL, for thirty-five years a practising physician of Brooklyn, died on June 18, at the age of sixty-three years. He was graduated from the New York Homeopathic Medical College in 1886, and had been connected with the staffs of the Peck Memorial, Cumberland Street, and Brooklyn Nursery and Infants' hospitals, and the Brooklyn home for consumptives.

Dr. SAMUEL B. RUBY of Union City, Indiana, died at his home on May 16, at the age of sixty-six years. He was licensed to practice medicine in Indiana in 1897.

Dr. MOSES REGINAL POLLOM of Thorntown, Ind., died on May 13, following an operation for brain tumor. He was a graduate of the Medical College of Indiana, Indianapolis, in 1904. He was president of the Boone County Medical Society in 1920.

Dr. ELIZABETH LAIN of Santa Rosa, Cal., died in a local hospital on May 17, at the age of fifty-six years. She was graduated from the Hahnemann Medical College of the Pacific in 1897.

Dr. CHARLES F. MCCARTHY, formerly of Franklin, R. I., died at his home in Winchester, Mass., on May 19, at the age of fifty-one years. He was graduated from the Long Island College Hospital in 1890.

Dr. THOMAS P. ALLEN of Pembroke, Ky., a graduate of the University of Louisville in 1884, died suddenly of heart disease on May 16, at the age of sixty-two years.

Dr. EDWARD BENNETT ROSA, a well-known research worker, chief physicist of the Bureau of Standards, Washington, D. C., died suddenly on May 17, at the age of sixty years. He was instructor in physics at the University of Wisconsin and professor of physics at Wesleyan University before becoming chief of the Bureau of Standards. He did notable work in science and electrical engineering and developed the physical side of the respiration calorimeter with Professor W. O. Atwater.

Dr. JAMES E. BROOKS of Blowing Rock, N. C., formerly a practitioner of Greensboro, died suddenly on May 20, at the age of fifty-seven years. He was one of the prime movers in the establishment of the State Sanatorium for Tuberculous Patients at Montrose, N. C.

Dr. JAMES L. SUDDARTH of Washington, D. C., for many years a member of the faculty of the Columbia and George Washington Universities, died at his home on May 25, at the age of eighty-one years. He was a graduate of the Georgetown University in 1868, and a member of the Medical Society of the District of Columbia. He served as an officer under Stonewall Jackson during the Civil War.

Dr. EDWARD ELIAS MATHER of Williamstown, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1871, died on May 19, at the age of seventy-seven years.

Dr. E. H. THOMAS of Argenta, Ill., a graduate of the College of Physicians and Surgeons, New York, in 1883, died at his home May 22, at the age of sixty-one years.

Dr. OSCAR DAVIS, a former health officer of Galveston, Texas, a graduate of Fort Worth School of Medicine in 1898, died suddenly in a local hospital, on May 25, at the age of fifty-two years.

Dr. WILIAM MANDES MARCKS of De Soto, Kan., a graduate of the University of Pennsylvania,

in 1861, died at his home on May 25, at the age of eighty-two years.

Dr. ARGUS B. SWISHER, a graduate of the Miami (Ohio) Medical College in 1882, died at his home in Marysville, Ohio, on May 24, at the age of sixty-seven years.

Dr. GILBERT INGALS of Mayfield, N. Y., a former resident of Gloversville, N. Y., died at his home on May 25, at the age of sixty-nine years.

Dr. JAMES F. MEEK of New York and South Norwalk, Conn., a graduate of McGill University, Montreal, Canada, in 1875, died at his home in South Norwalk, on May 29, at the age of seventy-three years. He was on the staffs of the Manhattan Eye and Ear Hospital, the Northern Dispensary, the West Side German Dispensary, and the New York Throat, Nose and Lung Hospital, and made numerous contributions to the literature of ophthalmology. He was secretary of the Norwalk Medical Society.

Dr. EVELINE P. BALLINTINE of Rochester, N. Y., a graduate of the University of Michigan in 1877, and former resident of Leroy, N. Y., died in a Rochester hospital on May 18, at the age of sixty-nine years. She was in charge of the psychopathic division of the hospital since its organization in 1904.

Dr. CHARLES S. VALCOUR of Nashua, N. H., a graduate of the Baltimore Medical College in 1895, died after a prolonged illness at his home, on May 22, at the age of forty-nine years.

Dr. ASA P. TAYLOR, a graduate of the Medical College of Chicago in 1878, died suddenly of heart disease in his office in Lexington, Ky., on May 22, at the age of sixty-four years.

Dr. GEORGE R. SPRATT of Coatesville, Pa., a graduate of the University of Pennsylvania in 1864, died following a stroke of apoplexy on May 23, at the age of eighty-two years.

Dr. RUFUS G. WILLIAMS of Dallas, Texas, a graduate of Tulane University, New Orleans, in 1870, died on May 23.

Dr. JESSE ALBERT BOLIN of Philadelphia, Pa., a graduate of Jefferson Medical College in 1881, and Coroner's physician in 1910, died on May 27, at the age of sixty-five years.

Dr. ALBERT E. BLOUGH of Marietta, Pa., died at his home on May 26, at the age of forty-six years. He was graduated from Medico-Chirurgical College, Philadelphia, in 1904.

Dr. A. L. SWINTON, a graduate of the University of Michigan in 1899, died suddenly of heart disease, at his home in Charlevoix, Mich., on May 24, at the age of forty-four years. He was mayor of Charlevoix at the time of his death.

Dr. JOHN MACDARMID, former mayor of De Land, Fla., died suddenly on a train near that place on May 23, at the age of fifty-one years. He was graduated from the Southern Medical College of Georgia in 1891.

Dr. JOHN S. MENDEL of Trevorton, Pa., died suddenly on May 26, at the age of sixty-one years. He was graduated from Jefferson Medical College in 1887.

Dr. BENJAMIN RUSH HOYT of Detroit, Mich., a graduate of the University of Michigan in 1872, died in a local hospital on May 20, at the age of seventy-two years.

Dr. BACHE MCEVERS EMMET of Ridgefield, Conn., a graduate of the College of Physicians and Surgeons, in 1867, formerly professor of gynecology in the College of Physicians and Surgeons, New York, died on May 27.

Dr. CHARLES F. FURRAY, a retired physician of Omaha, Neb., died suddenly at his home, on May 19, at the age of fifty years. He was a graduate of the Creighton Medical College of the University of Nebraska.

Dr. WILLIAM T. JOHNSON, a graduate of the Missouri Medical College, St. Louis, in 1894, died at his home in Eldorado, Ill., on May 24, at the age of fifty-four years.

Dr. E. R. HUTCHINS, a former Des Moines physician, at one time a professor in Jefferson Medical College, died at Lake Okoboji on May 26, at the age of eighty years.

Dr. HERMAN VOSS, a former practitioner of Milwaukee, a graduate of the University of Leipsic, died in Racine, Wis., on May 27, at the age of sixty-six years.

Dr. JOSHUA D. JANNEY died at Riverton, N. J., on June 15, at the age of ninety years. He was graduated from Starling Medical College in the class of 1865.

Dr. DWIGHT DUDLEY of Endicott, N. Y., died after a prolonged illness on May 19, at the age of eighty years. He was graduated from the College of Physicians and Surgeons, New York, in 1864, and practiced medicine for many years in Maine, N. Y.

Dr. ALLAN G. NEATHERY of Farmersville, Tex., died suddenly on June 2, at the age of fifty-nine years. He was graduated from the Memphis Hospital College of Medicine in 1888.

Dr. THOMAS C. DOYLE of Orangeburg, S. C., died following a stroke of apoplexy on June 3, at the age of fifty-five years. He was graduated from the University of Maryland School of Medicine in 1889.

Dr. FRANK A. PALMER, formerly of Ilionite, N. Y., died of pneumonia at his home in Mechanicsville, N. Y., on June 1, at the age of sixty-one years. He was graduated from the Albany Medical College in 1882.

Dr. CHARLES TEUBNER, a graduate of New York University Medical College in 1885, died at Oxnard, Cal., on June 8, at the age of sixty-five years.

Dr. JOSHUA D. JANNEY of Roverton, N. J., a graduate of Starling Medical College in 1865, died on June 15, at the age of ninety years.

Dr. GEORGE F. BUTLER of Chicago, died of heart disease on the train while returning from Boston on June 21, at the age of fifty-one years. He was a graduate of Rush Medical College in 1889, and the author of several medical and other books.

Dr. HERBERT E. NOBLE of Toledo, Ohio, a graduate of the Detroit Medical College in 1879, died at his home on May 29, at the age of sixty-six years.

Dr. RICHARD KALISH died at his home in New York City on June 21, at the age of sixty-seven years. He was graduated from Bellevue Hospital Medical College in 1875. He was a fellow of the American College of Surgeons, a member of the American Medical Association, and the New York Academy of Medicine. He was consulting ophthalmologist to the Knickerbocker, City, Sea View, St. Johns, and Long Island City hospitals.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 10, 1921.

Dentistry and Public Health.—A bill to amend the Dentists' Act was introduced into the House of Commons on May 4, last. But before explaining the provisions of the bill it will be well to describe briefly the situation as regards dentistry at the present time in this country. The great value of good teeth and a clean mouth in preventing disease and in maintaining good general health has become a matter of common knowledge within the past few years. While the influence of the condition of the teeth and mouth upon the health may have been somewhat exaggerated by a considerable number of medical men, there is no doubt that many serious illnesses may be partly induced or influenced for the worse by diseased teeth. It is not long ago that the practice of dentistry consisted mainly in the extraction of teeth and the provision of artificial substitutes. Conservative dentistry, the object of which was the preservation of the teeth, brought it into relation with general medicine. From this upward progress of dentistry two advances were made: The institution in England of a special course of training, and the granting of a license in dental surgery by the Royal College of Surgeons of England, and the second step forward was the passing of the Dentists' Act in 1878, which created a register of dentists under the control of the General Medical Council and made illegal the use of the titles "dentist" or "dental practitioner" by unregistered persons. It was deemed by those who were responsible for the drafting of the act and by Parliament that prohibition of title would be sufficient means of distinction between the qualified and the unqualified, and a criterion by which the public could judge. From that point of view the act has been a failure, for the opportunities for evasion without definite contravention of the act are manifold and obvious. Only a very small proportion of the public knows and appreciates the difference between the qualified and the unqualified, and the evils associated with practice by the latter have increased so rapidly in recent years as to have become a source of real danger to the community. The number of dentists admitted to the register by virtue of the possession of a qualification has only about balanced the loss by death or retirement, so that the total has remained nearly stationary. On the other hand, unqualified practitioners have increased by leaps and bounds. This state of affairs led to the appointment of a Departmental Committee to inquire into the extent and gravity of the evils of dental practice by persons not qualified under the Dentists' Act. This committee issued a report in 1919 which emphasized in vigorous language the danger to the public and the degradation of the profession associated with the practice of dentistry by incompetent persons subject to no professional control. The bill just brought forward is founded upon and follows closely the recommendations of the report so far as they are concerned with registration and control. The main provisions of the bill all turn upon the first section, which states: No person shall, unless he is registered under the Dentists' Act of 1878, practice or hold himself out, whether directly or by implication, as practising or being prepared to practise dentistry for fee or reward.

Honors for Medical Men.—Among the honors conferred on the occasion of the King's birthday are Commander of the Order of the Bath for Llewellyn Southworth Lloyd, Assistant Secretary to the Department of Scientific and Industrial Research since its formation. Knighthoods for Arthur Keith, M.D., F.R.C.S., LL.D., Hunterian Professor and Conservator of the Royal College of Surgeons; Thomas Lewis, C.B.E., M.D., F.R.C.P., D.S.C., F.R.S., Hon. Consulting Physician since April, 1918, to the Ministry of Pensions; Sidney Russell Wells, M.D., B.Sc., M.R.C.P., M.R.C.S., Vice-Chancellor of the University of London, Representative of the University of London on the General Medical Council, and F. Conway Dyer, M.D., ex-President of the College of Surgeons, Ireland, Lieut.-Colonel, R.A.M.C., and Operating Surgeon to King George V Military Hospital in Dublin, Hon. Surgeon to Lord-Lieutenant of Ireland, Chairman of House of Industry Hospitals, H. M. Inspector of Anatomy in Ireland.

Report on Postgraduate Medical Education in Great Britain.—The report of the Athlone Committee, appointed to consider the question of postgraduate medical education in Great Britain, is to be issued soon. Of course, the subject is of the first importance, and is one that has been referred to frequently in these letters. The existing state of affairs with regard to postgraduate medical facilities in Great Britain is very unsatisfactory. It is the great desire of medical men of this country, and particularly those of London, to attract American physicians and surgeons here for postgraduate training. Before the war the great majority of these betook themselves to Berlin and Vienna, where opportunities were given them which were lacking in London or in any of the British medical centers. As said before, it is the desire of the medical profession in this country to induce postgraduate medical students from America to train in the British medical schools and hospitals. However, up to the present time there has been no coordinated effort to offer opportunities, equal to those offered in Germany, for postgraduate medical study. A few men have worked hard with this object in view, but they have not been adequately supported. It is hoped that the new report, which is completed and only awaits the approval of the Minister of Health, will point the way to a better state of affairs. In order that proper facilities for this kind of medical teaching may be provided a special hospital, in which teaching is confined to postgraduate students, is necessary. Moreover, the Ministry of Health is expected to cooperate with though not to dominate, the work. The London medical schools are among the best in the world and clinical material abounds. Money and organization are alone required to make a success of the scheme. It hangs fire, and the point may be emphasized that, unless steps are promptly taken

to make of London a great medical postgraduate center, the chance of doing so will disappear, never to return.

Industrial Disease.—The prevention of industrial disease through the instrumentality of the joint industrial councils has somewhat escaped attention in this country. Many of the councils have set up safety and welfare committees to investigate and report on industrial disease, conditions of work, and the administration of welfare regulations. In the boot and shoe trade the Welfare Committee's recommendations included prohibition of underground workrooms in any new works and after a period of three years in any existing work places; insistence of cleanliness of windows, floors, walls, and taps in all work places; provision of adequate and suitably shaded artificial light, of washing accommodation and first-aid equipment. In the pottery trade 27 firms have complied with all the recommendations made by the council, 40 with six of them, 30 with five, 18 with four, and 22 with three. Dr. E. Collis, the Professor of Preventive Medicine at the University College, Cardiff, and Doctor Legge of the Home Office are among the experts who have given help by addressing the councils.

Bone-Forming Foods.—Dr. Edward Mellanby, Professor of Pharmacology at the University of Sheffield, lectured at the Royal College of Surgeons, London, on June 6, concerning some actions of foodstuffs in the production and treatment of disease. Dealing with elements of diet-aiding and preventing the proper calcification and growth of bones and teeth, the lecturer said that up to the present time the idea that you could feed a child so that it could digest anything had never been previously considered. Food was becoming more and more manipulated, and so we ate more and more manufactured foods, manufacturers seeking to flatter our tastes. We were ignorant as to food, but we should be able to tell a mother how to feed a child so as to obtain certain results. The factors in the diet of children affected not merely bones and teeth, but had their influence in other diseases. He explained that there was more calcium in the bones of dogs fed on suet and butter than in those fed on lard. According to the diet given to dogs, one obtained good or bad calcification. He next drew attention to the antirachitic action of fats, of which the best were cod-liver oil, butter, and suet; peanut, lard, cottonseed, and rape oil were only moderately good for calcifying processes. Vegetables contained a smaller quantity of vitamines than animal fats. Bread was a potent factor in the development of rickets; this had been ascertained by experiments made with dogs. Meat with all the fat off had an antirachitic effect, while the contrary was the case with bread, which made rickets worse.

Society for the Prevention of Venereal Disease.—The second annual meeting of the Society for the Prevention of Venereal Disease was held at the house of the Royal Society of Medicine on June 6, last. Lord Willoughby de Broke, who presided, said that venereal disease was still proceeding at an alarming rate and was a grave public danger, in spite of official policy, which consisted of recommending chastity and advising the infected to go to a doctor. But exhortation had failed, and a new departure was absolutely necessary. It might take the form of compulsory measures, but the objection was that these were highly contentious, and involved legislation and consequent delay. In the last few days the Ministry of Health had committed itself, in a circular, to a statement that it was the duty of all individuals who had incurred risk of infection to cleanse themselves thoroughly and immediately to diminish the risk. This, Lord Willoughby urged, affirmed the society's policy of self-disinfection. The society had been at pains to persuade the Ministry of Health to alter the Act of 1917, so that chemists might sell the necessary disinfectants. The Government, however, said they could not give official support to self-disinfection as a policy, and he wondered how far this attitude was due to political considerations. The right policy for the society was to welcome the frank admission of the Ministry of Health and to approach the Minister with a view to securing the sale of proper disinfectants, accompanied by proper instructions. If the Government would not take the responsibility of issuing such instructions, the proper body to do so was that society, which would undertake to recommend what should be sold, and would be responsible for the accompanying instructions. He moved a resolution recommending formal application to the Ministry of Health for sanction of the preparation and sale, under the society's control, of materials for self-disinfection. The resolution was seconded by Lieutenant-General Sir Francis Lloyd and Lady Askwith. The work of the society was recounted in a report read by the Hon. Secretary, Mr. Wansey Bayly, who stated that the number of county and borough councils that had adopted the society's policy had increased from 12 to 20.

1. Congenital Malformations of the Vertebræ. Nathaniel Mills.
2. Principles of Posture, with Special Reference to the Mechanics of the Hip-Joint. Mabel Elsworth Todd.

1. Congenital Malformations of the Vertebræ.—Nathaniel Mills classifies congenital malformations of the vertebræ under the categories of defects in development, changes in type, and changes in relation. These abnormalities are held to be of quite common occurrence, as exemplified in the plates of one hundred consecutive cases of scoliosis from the *x*-ray files of the New York Orthopedic Dispensary and Hospital. In this series there were thirty-eight instances of defects in development, sixty-five instances of change in type, and thirty-nine instances of change in relation.

2. The Treatment of the Toxemia of Early and Late Pregnancy.—Edward P. Davis holds that statistics regarding recovery from the toxemia of pregnancy, whether early or late, are misleading. No one can accurately estimate the resisting power of the patient or the virulence of the toxins. When symptoms have subsided and the patient is apparently safe, complications may develop which may end life. Under any reasonable method of treatment, a series of cases can be conducted with a low mortality, followed by a group of cases in which no method of treatment is of much value and where the mortality becomes excessively high. Practically speaking, the most important points concerning the subject are the familiar facts that pregnant patients require special care; that the toxemia of pregnancy, early or late, is serious, demanding hospital service; that in a well-appointed hospital, prompt and efficient treatment can be given, guided by clinical observation and laboratory examinations, and that the mother's chance for recovery depends on early diagnosis, prompt and thorough treatment, and the avoidance of whatever may be depressing to the vital forces.

5. Syphilitic Iritis: Its Racial Incidence and Its Association with Secondary Syphilis and with Neurosyphilis.—Ernest L. Zimmermann bases this communication on a series of eighty-four cases of acute syphilitic iritis observed in the syphilis department of the Johns Hopkins Dispensary between 1917 and 1921, and thirty-five cases observed in the syphilis clinic of the Baltimore Eye, Ear, and Throat Hospital during 1920. These cases were thus divided according to race and sex: thirteen white males, thirteen white females, fifty-five negro males and thirty-eight negro females. In the former clinic 4400 syphilitics were examined during the four-year period, of whom 2600 were negroes. There were twenty cases of acute syphilitic iritis among the white patients and sixty-four among the negroes, an incidence of 1.1 per cent. in the former and 3.2 per cent. in the latter. Fournier estimates that from 3 to 4 per cent. of syphilitics develop iritis. Boeck found 139 cases of iritis among 2344 syphilitics, an incidence of 5.37 per cent. That these results are so much higher than those in the writer's series is explained by the fact that the modern syphilis clinic, owing to the recent advances in diagnosis and treatment, includes a much greater number of asymptomatic syphilitics. Among the 228 white patients with early secondary syphilis in the Johns Hopkins Clinic there were four, or 1.76 per cent., with acute iritis; among the 279 negroes, iritis occurred in thirty-six, or 12.9 per cent. From the observation of these cases the writer concludes that both in early and secondary syphilis and subsequently in the course of the disease, the negro is more liable to iritis than is the white man. Iritis occurs in more than 10 per cent. of all cases of early secondary syphilis in the negro, and is most often associated with follicular syphilides. Abnormalities in the cerebrospinal fluid of partially treated syphilitics with iritis occur with no greater frequency than in the fluids of treated patients who have not had iritis.

10. The Toxicity and Trypanocidal Activity of Sodium Arsphenamine.—Jay Frank Schamberg, John A. Kolmer and George W. Raiziss summarize their observations on this subject as follows: 1. The highest tolerated dose of sodium arsphenamine for white rats by intravenous injection was found to be from 212 to 215 mg. per kilogram of weight. The average tolerated dose of arsphenamine was 105 mg. and of neoarsphenamine, 200 mg. per kilogram. 2. The smallest trypanocidal doses of sodium arsphenamine varied from 16 to 24 mg. per kilogram of weight; the smallest trypanocidal dose of arsphenamine was 5 mg., and of neoarsphenamine, 9 mg. per kilogram. 3. The therapeutic dose (dosis curativa) of sodium arsphenamine was from eight to thirteen times less than the highest tolerated dose (dosis tolerata) which expresses the therapeutic index of this compound. The therapeutic dose of arsphenamine was twenty-one times less than the tolerated dose, and the therapeutic dose of neoarsphenamine was twenty-two times less. 4. Therefore, while sodium arsphenamine possesses the low toxicity of neoarsphenamine, it is much inferior to both arsphenamine and neoarsphenamine in trypanocidal or curative activity. 5. The true gage of a remedy is expressed by its chemotherapeutic index, *i.e.* the relation of the curative to the toxic doses.

3. A New General Anesthetic: Its Theory and Practice.—R. L. Mackenzie Wallis and C. Langton Hewer describe the manufacture of and clinical results from the use of a new anesthetic known under the trade name of "Ethanesal." Their investigations showed that certain ketones in ether were largely responsible for the anesthetic properties of the ether. Good anesthetic ethers, free from aldehydes, mercaptans, etc., when treated with finely divided permanganate, yielded a pleasant smelling residue instead of the evil smelling residues previously obtained. This residue proved to contain ketones, and these compounds appeared to be the essential element in the production of a food and safe anesthetic. The mixture of ketones proved to be very potent, and it was necessary to use a volatile solvent. In view of the readiness with which ordinary ether can be purified, this compound was selected as the solvent. Into this pure ether the mixed ketones were placed in varying proportions, and the mixtures so obtained were found to be capable of producing anesthesia. The anesthetic action was enhanced if the mixed ketones were first treated with carbon dioxide and ethylene. The ketones used comprise those in the middle of the series, and a loose chemical combination between these substances and the carbon dioxide and ethylene apparently results. In attempting to purify the ether, therefore, the discovery was made of the importance of certain impurities—the ketones. This opens up a wide field for further investigation, and much further work is necessary before it can be said that the ideal general anesthetic has been obtained. From their clinical experience in 250 cases, on 200 of which they have detailed reports, the writers found that this agent is less toxic than chloroform or ether, and the safety margin is greater than with ether. It is less irritating to the respiratory passages than ether, and consequently there is less risk of subsequent bronchitis and pneumonia; the induction of anesthesia is also rendered easier. Postanesthetic vomiting is less than with chloroform or ether. The taste and smell noticed afterward by the patient are very much less than with ether, and are generally absent.

2. Infective Arthritis and Allied Conditions: with Special Reference to Etiology and Treatment.—W. H. Wilcox, in discussing the etiological factors concerned in the many forms of chronic rheumatism of doubtful origin, takes into consideration the relative importance of sex, age, race, family history, mental strain, and

debility, trauma and physical strain, exposure to cold and wet, pregnancy and parturition, disease of the nervous system, faulty metabolism, rheumatic fever, and infective causes. The only forms of arthritis to which he gives special discussion are rheumatoid arthritis, arthritis deformans, osteoarthritis, and chronic villous arthritis, each of which is in all probability due to an infective cause of nonspecific origin. In looking for the cause of infective arthritis one must consider infection from teeth, intestinal infections, tonsils and adenoids. Treatment is indicated by the revelations of thorough investigation as to causation. Vaccine treatment is of value, but it cannot be too strongly insisted upon that it must be accompanied by removal of the causal infections. Electrical treatment, massage, and diet are to be considered. The prognosis is favorable in early cases which are thoroughly investigated and treated along the lines indicated. In cases of long standing the inflammatory changes are often progressive in nature and removal of the primary cause may do little good because the infective process is being carried on by a secondary intestinal infection. In such cases everything possible should be done to remove both the primary and the secondary causes of infection, and when the signs of active inflammation in the joints have ceased measures should be taken to improve the mobility of the joints and muscular tone by massage and movements.

7. Makeshifts in Practice. J. G. Watkins.
8. Tracheal Diphtheria. Trevor A. Lawder.

1. The Surgical Treatment of Neuralgia.—Sir William Thorburn uses the term "neuralgia" in its widest sense. It connotes no pathology and no etiology, but merely indicates pain in the distribution of one or more nerves, not due to any obvious gross lesion; in fact, he uses it in the sense in which it is commonly employed in general practice, and even by the laity. This being so, it is necessary in the first pace to realize that such pain may be due to very varying conditions, by no means all of which call for surgical treatment; and the first essential in connection with treatment of any kind is an accurate diagnosis, if such can be made, of the real cause of the neuralgic pain. For purposes of convenience he divides the varying types of neuralgia into five groups: 1. Neuralgias due to certain *general conditions*, probably toxic in their nature, such as anemia, malaria, gout, rheumatism, and syphilis. None of these call for surgical treatment. 2. Cases due to *pressure upon nerves*, in the great majority of which surgery will call for consideration. If an accurate diagnosis is made, the question of treatment will follow almost as a matter of course. 3. Neuralgias associated with *locomotor ataxia*, sometimes with other parasyphilitic diseases of the nervous system. These are placed under a separate group because the pain is often severe, very long-standing, and calls for a somewhat special line of treatment. 4. Neuralgias due to *intraneural lesions*. Under this category, among others, come cases of causalgia, which became familiar during the war. The writer's strong feeling is that in all cases of persistent neuralgia in which one is reasonably confident that the lesion lies within the nerve trunk, the proper course to pursue is to expose the trunk as far as possible from end to end. 5 "*Ganglionic neuralgia*," socalled, provisionally, on the assumption that the essential lesion lies not within the nerve trunk, but in the ganglion with which such nerve trunk is associated, the two outstanding instances being trigeminal neuralgia and postherpetic neuralgia. To deal with the last first, there is a reasonable presumption that persistent neuralgia after herpes is due to a lesion of the posterior root ganglion of the nerve concerned, and that division of the posterior roots involved, with or without removal of the ganglia, ought to cure the condition. Of trigeminal neuralgia the writer has had many complete and certainly permanent cures by removal of the Gasserian ganglion.

4. Dried Milk as a Food for Infants.—Robert J. Blackham sums up the position of dried milk as a food for infants. 1. *Comparability with Fresh Milk.* Some authorities, including numerous French and Belgian doctors, regard it as *un véritable aliment de choix*, and consider it superior to sterilized cow's milk or even humanized cow's milk. Others regard it as a temporary diet, to be given for a short time when other foods disagree. In most cases, increased experience with the product has led to greater confidence in its employment. 2. *Nutritional Value.* The French writers consider dried milk safer than town milk, and of equal nutritional value. They regard it as specially suitable to supplement breast feeding. 3. *Digestibility.* All investigators have found it better tolerated than other foods in digestive troubles. Goodhart and Still say: "The chief virtue in dried milk lies in the fineness and softness of the curd, which is so much more digestible than fresh milk. Some infants, that cannot digest even peptonized milk, thrive on dried milk." 4. *Suitability for Warm Weather.* The French authorities and most municipal infant welfare centers have found it of special value in warm weather. 5. *Use in Pathological Conditions.* In his experience, dried milk has been of special value to infants who have been doing badly, especially among the poorer classes.

1. The Ulcer Syndrome without Ulcer.—Alfred C. Croftan emphasizes the points that many gastric ulcers run their whole course to hemorrhage, perforation, accidental discovery at autopsy or in the course of laparotomy, or to spontaneous cure, without any symptoms whatever, and that, on the other hand, the whole syndrome may be present without the ulcer. In interpreting the results of treatment one should be careful in speaking of a cure. As the diagnosis remains uncertain in a large proportion of the cases, so does the cure. One sees too many "healed" ulcers to have much faith in the permanency of the cure unless by surgery. The majority of the cured ulcer cases, in the writer's opinion, were ulcer syndrome patients without ulcer and not ulcer patients at all.

4. The Feeding Problem in the Light of Modern Investigation. H. Booker Mills.

3. Referred Pain and Pain by Extension in Visceral Disease.—W. H. Foreman, in the fifth of this series of contributions dealing with pain, states that an intimate relation exists between somatic and visceral structures through spinal and sympathetic nerves, mediation occurring in the cord, the reflex being in either direction. The great mass of stimuli, and especially visceral stimuli, are never adequate to reach consciousness, and are only concerned in unconscious reflex influence. The nerve synapses constitute a natural barrier between visceral and somatic structures and the conscious mind; this is evident in visceral structures. This natural barrier of inhibition is broken down in organic or functional disease of the viscera or nerve centers by increasing the strength of the stimuli or lowering the threshold of nerve resistance. Reflexes occur over the parasympathetic system in the same manner as over the sympathetic and spinal systems.

March 23-5, 1921, xxxv, 13.

Progress of Our Knowledge of Diphtheria.—This issue is devoted wholly to articles on diphtheria. The first is by Martin and Loiseau and is limited to bacteriology. Not long ago, say the authors, it was regarded as almost too simple a matter to make the diagnosis of the disease from the presence of the bacillus. Even a novice could swab the throat and in 24 hours show a culture on coagulated serum of a Gram-positive bacillus which indicated the exciting cause of the disease. This, however, has become a small part of the laboratory man's activities, for the problem has been extended to the examination of smears from the healthy with special reference to healthy carriers and here the trouble began; for numerous microorganisms have continued to confuse the student and now only an accomplished bacteriologist can make the differentiation. Culture media, staining agents, agglutination tests, have to be made the subjects of intensive study. It has become evident that among undoubted diphtheria bacilli, numerous normal variations occur although the effort to isolate these varieties does not lead to practical results. Metachromatic granulations and polar corpuscles have received a good deal of attention in connection with the degree of virulence, but without definite results. Other criteria have also failed, as the production of acid in a carbohydrate medium. In this connection comes up the subject of facultative anaerobiosis of the true diphtheria bacillus. The typical organism being either long or medium, a question of the day of great importance deals with the existence of the short bacillus of some authors—is this a true morphological variant? The authors answer this question in the negative. A subject whose throat exhibits only the short bacillus is not a carrier. Darré discussed the diagnosis of a typical diphtheritic angina. He described in succession catarrhal and pultaceous forms, lacunar and herpetic forms, and in the same connection the socalled cryptogenetic form in which the throat may appear normal. This form is usually treated late and hence its recognition is a matter of great importance. In some of these cases membrane may be found on the posterior aspect of the soft palate, while in others diphtheria is masked by an apparent catarrhal or lacunar angina. The author devotes a good deal of space to what he terms the erythematous form. While some anginas occupy the entire anginal region others are restricted to a single locality. Simple erythema may be of either kind. In certain cases the symptoms are limited to slight discomfort on swallowing with a little swelling at some point in the throat; with these minimal symptoms, which are apt to be encountered in adults and large children, the appearance of a lymph-node reaction may cause suspicion of diphtheria. The pultaceous deposit, which may or may not be present in these anomalous cases, bears little resemblance to a false membrane but it is a fact that every transition is found between this kind of deposit and the firmest diphtheritic membrane. To go more thoroughly into the subject of cryptogenic diphtheria the author states that the original deposit may be in the nasopharynx, in Luschka's tonsil. The presence of the Klebs-Loeffler bacillus may give rise to the question "has a simple angina occurred in a bacillus carrier, or can the latter alone set up the picture of simple angina?" The author holds the latter view.

Melanodermas of the Addisonian Type.—Sézary states that the symptom of melanoderma was what led Addison to investigate the disease which bears his name. This with the special asthenia was indeed almost sufficient for diagnosis. But Addison was bothered to find it absent in certain cases in which the suprarenal cortex was practically destroyed, and on this account expressed the view that there might be a nervous component to explain the exceptional case. Schmidt of Rotterdam succeeded in showing that the lesions of the cortex had some destructive action on the solar plexus so that it was thought probable that the pigmentation might be due to the associated nerve lesions. Today we recognize two distinct processes, a destruction of the cortex and hypoadrenia, which is responsible for an autointoxication, and a neurogenic syndrome under which belongs the melanoderma. In other words, it has not been possible to connect melanoderma with hypoadrenia. Can we account for it on the other hypothesis of lesions of the sympathetic? As far back as 1866 Jaccoud invoked the sympathetic to explain the pigmentation, but his reasoning was insufficient for this purpose. Gradually, through the labors of numerous investigators the thesis was placed that any irritation of the solar plexus and semilunar ganglia would if sufficiently powerful give rise to pigmentation of the skin and mucosæ (Chauffard). The deposit of pigment is only an overaction of a normal process. Presumably it is not different in its nature from the racial pigmentation of the negro and dark races in general. The Addisonian presents an acquired instead of an hereditary pigmentation. Given the predisposition, different factors will cause the hyperpigmentation. We cannot state to what extent, if any, it is a defense reaction and to what a sign of inferiority. The latter seems the more likely to suit the conditions. There may also be some kinship with senile pigmentation. Certain experiments have shown that depreciated nutrition will determine an accumulation of melanine in the epidermis. In not a few cases opotherapy has caused the pigment to fade and even to disappear, and in syphilis of the adrenals with pigmentation, the action of antisyphilitic remedies has produced the same result. But despite the activity of the sympathetic in the production of melanoderma, not only is the mechanism far from clear, but we know that the pigmentation may occur without any neurotic component whatever. The positive per cent. is at least 73, but this leaves a large margin without a neurogenic component. We must, therefore, to solve the mystery, study cases of melanoderma of the Addison type, in which both adrenals and sympathetic are intact. One type of these is of hepatic origin, beginning with the socalled "liver spots," while another is of thyroid origin. As far as known the liver and the thyroid, respectively, in such cases, are in a state of dysfunction or insufficiency. Jointly, then, there is evidence of an endocrinic type. Melanoderma *per se* has no diagnostic value but must be studied along with its concomitant symptoms. In extreme melanosis from lousiness, the adrenals may be found organically diseased, showing that the normal tendency to pigmentation is increased.

Finska Läkaresällskapets Handlingar.

January-February, 1921, lxiii, 1-2.

Sex and Pathology.—Ehrstrom gives an interesting account of the sex ratios in the incidence of disease. It is of course problematical how much of this influence is really sexual and how much due to mode of life. The material comes from various sources including personal statistics. The author first lists the affections in which the ratio of incidence favors the male. Gout leads off with the sex ratio of 40 to 1, while at the other extreme are appendicitis and nephrosclerosis with 3 to 2. With male sex strongly predominating we find Thomsen's disease, hemophilia and color blindness with 10 to 1; Leber's disease gives 6 to 1, and progressive muscular atrophy 5 to 1. In four affections the ratio is 3 to 1 in favor of the male—emphysema, hay fever, chloroma, and Hirschsprung's disease. The ratio of 2 to 1 is seen in diabetes mellitus, bronchial asthma, hemeralopia, paralysis agitans and hereditary nystagmus. In one affection in which the male predominates —arteriosclerosis—no exact figures are given. Proceeding now to the affections in which the female leads we find that chlorosis tops the list, no ratio being given, while Heberden's nodes is also without figures, the two affections being almost peculiar to women. Of actual statistical ratios vasomotor neuroses lead with 20 to 1, while at the other extreme is migraine with 3 to 2. Basedow's disease affects women in the proportion of 15 to 1, osteomalacia in 10 to 1, arthritis deformans in 6 to 1, myxedema and hysteria 5 to 1, ordinary goiter 4 to 1, gallstones 3 to 1, scleroderma 3 to 1, endemic goiter 2 to 1, and chorea minor 2 to 1.

Book Reviews.

THE HUMAN ATMOSPHERE. (The Aura). By WALTER J. KILNER, B.A., M.B. (Cantab.), M.R.C.P. (London), late Electrician to St. Thomas's Hospital, London. New York: E. P. Dutton & Co., 1920.

THIS is an enlarged and amended edition of the same work brought out in 1911 by the Rebman Company, which was then sold with the necessary screens for adjusting the vision. When the eye has been adjusted by looking at fair daylight through a flat cell containing a solution of dicyanin, the author claims that it is possible to distinguish three or four layers of some kind of emanation surrounding the body. This varies with age, sex and health and, by the use of complementary color screens, it is possible to distinguish variations in color and texture which have a diagnostic value in disease. The author considers this a manifestation of light and believes that it consists of rays shorter than violet, of which the human eye, unless specially sensitized, does not take cognizance. He tries to obtain some kind of order in relation to these phenomena of apparent luminosity and he gives his personal experience with a great many cases through a long period of years.

INSTINCT AND THE UNCONSCIOUS. A contribution to a biological theory of the psychoneuroses. By W. H. R. RIVERS, M.D., D.Sc., LL.D., F.R.S., London. Cambridge University Press, 1920.

THIS is a work which well repays careful study by the psychologist and the psychopathologist. Clinical psychology needs to be harmonized with the whole body of biological and physiological facts and knowledge, and the results expressed in clear and special language. Here a trained observer and psychologist is interpreting facts with greater detachment and a wider view than the special psychologist from the clinical side. Dr. Rivers considers especially the biological function by which experience passes into the region of the unconscious. This he calls "suppression," and shows that it occurs without the intervention of volution, and that it really is a specially complete form of forgetting. He limits the unconscious to experiences and complexes of this kind which are not to be brought into the field of consciousness by the ordinary processes of memory or association. Every living process in the animal involves, not only activity directed to a special end, but the inhibition of tendencies to activities of other kinds. Here the author differs from the followers of Freud (not Freud himself), and he asserts that the main factor in life is not self-reproduction or sex, but self-preservation. Dr. Rivers has as his central contention that the same biological principles operate at the psychological levels of development as at the sensorimotor and reflex levels. Where Dr. Rivers differs from Freud most widely is in the matter of the "censorship." The book must be read in order to appreciate the argument; but it is a timely protest against the exaggerated conceptions of the differing schools. One main contention is that suppression is a normal and salutary process and that some buried complexes are only to be brought to the surface with danger to patients.

A SYNOPSIS OF SURGERY. Illustrated. By ERNEST W. HEY GROVES, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.). Surgeon to the Bristol General Hospital; Consulting Surgeon to the Cossham Hospital; Lecturer on Surgery at Bristol University; Examiner in Surgery, University of London. Fifth Edition. Price, $3.00. New York: William Wood & Company, 1921.

IN this well-known synopsis the reader will find an admirable epitome of the main facts in surgery. It is assumed that a student has already read through a standard textbook, and that he is anxious to summarize and systematize his knowledge. If used for this purpose the book will prove of the greatest value; but it is useless as a short cut for the beginner. The special arrangement of headings and indented margins, together with the different kinds of type, enables the reader to see the scope of any subject at a glance. Special sections are inserted dealing with the difficulties of diagnosis in certain regions, and also with the special examination of these parts. The new edition contains the main results of the War Surgery, and also a few additional illustrations, but the increase in size is but slight. The paper, print and general makeup of the volume leave nothing to be desired.

OLD AT FORTY OR YOUNG AT SIXTY. By ROBERT S. CARROLL, M.D. New York: The Macmillan Company, 1920.

THIS is one of the many small books which have been written to attract the attention of those out of health or of those who wish to preserve or increase what they have. It is a guide for those who wish to help themselves. Among the many it is distinguished by common sense and is eminently sane and workable. It deals on physical, mental, and spiritual lines in the restoration of the balance of all the vital factors and the application of self-control. It would save the busy practitioner a good deal of time if he were to take this book and mark it as part of his instructions for his patient to follow, for the disadvantage is that the inculcation of principles, such as this and similar books contain, must be supplemented by their application to individual cases.

A COMPEND OF DISEASES OF THE SKIN. By JAY FRANK SCHAMBERG, A.B., M.D., Professor of Dermatology and Syphilology, Graduate School of Medicine, University of Pennsylvania; Fellow of the College of Physicians of Philadelphia; President of the American Dermatological Association, etc., etc. Sixth edition. Revised and enlarged, with 119 illustrations. Philadelphia: P. Blakiston's Son & Co.

THIS little compend is well known. In its revised form it retains the features which made it popular on its first appearance, notably the tables of differential diagnosis and the sections on treatment. Except in the chapter on syphilis, this edition differs but little from the previous one. Some of the "derivations" are capable of improvement, especially those which are decorated with the weird printers' Greek.

ANÆSTHETICS. Their Uses and Administration. By DUDLEY WILMOT BUXTON, M.D., B.S. Member of the Royal College of Physicians; sometime President of the Society of Anæsthetists; Member of University College; Consulting Anæsthetist to University College Hospital and to the National Hospital for Paralysis and Epilepsy, Queen Square, and to the Royal Dental Hospital of London; late Anæsthetist to King George Hospital, and Administrator of Anæsthetics and Lecturer in University College Hospital. Sixth edition. Philadelphia: P. Blakiston's Son & Co., 1920.

THIS standard work on anesthetics has been thoroughly revised and brought in line with recent advances. Two important new sections are those dealing with shock and hemorrhage, and the author has provided a brief summary of the various theories of shock and of the necessary treatment before, during, and after anesthesia. Other additions include the subjects of angioneurotic edema, massage of the heart, posture of the patient, anociassociation, local analgesia and spinal anesthesia. The book begins with a brief historical sketch, and closes with an important chapter on the medicolegal aspects of the administration of anesthetics. The general arrangement of the chapters necessitates some overlapping and repetition, but this is not a disadvantage. The practitioner will find in this volume all that he needs on the subject of anesthetics; and the carefully writen descriptions of methods of administration will impress upon him the fact that general anesthetics have their dangers as well as their blessings.

PATIENT'S HANDBOOK ON THE TREATMENT OF DIABETES MELLITUS. By THOMAS W. EDGAR, M.D., Boston: Richard G. Badger, 1920.

THE aim of this booklet is the cooperation of the patient with his physician through intelligent understanding of the details which he is instructed to carry out. The author states that he is not in accordance with the present mode of treatment, but with exceptions and cautions, the treatments which he lays down for use are those which are usually followed; and he suggests that he is using a serum and a medicinal infusion of his own discovery. The diet tables are comprehensive and useful. But in essence the book is for use in the author's own practice.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 25, 1921.

THE PRESIDENT, DR GEORGE GRAY WARD, JR., IN THE CHAIR.

Report of the Comitia Minora.—This body recommended that in view of the fact that the Professional Guild of Kings County had begun proceedings seeking to enjoin the Commissioner of the State Narcotic Commission from enforcing the regulations issued in December, 1920, no further action should be taken in that matter by the society at the present time. Another recommendation instructed all delegates to the State Society to oppose any measures favoring the establishment of health centers and to instruct delegates to the A. M. A. to oppose resolutions having for their object the furthering of the health center plan.

These recommendations were adopted.

THE COMITIA MINORA, sitting as a reference committee on the resolutions of Dr. Byron C. Darling, submitted at the meeting of March 28, 1921, which provided for a comprehensive survey of medical practice in the United States, the establishment of a weekly news organ, and the appointment of an executive secretary in common for the State and County societies, reported that it had considered these resolutions, and had recommended that no action be taken thereon for the following reasons: (1) To undertake a survey of medical practice as outlined in the resolutions would require an appropriation beyond the means of the society. (2) The matter of a news organ was now pending before the committee on civic policy. (3) The office of executive secretary for the State society was created by the last House of Delegates; the income of the society did not warrant such increased expenditure.

This recommendation was adopted by the society.

Resolutions Opposing Proposed Amendment of Volstead Act.—Dr. J. P. DAVIN introduced a resolution, which was read by the secretary, to the effect that whereas an amendment to the Volstead act was about to be proposed to prevent the manufacture, sale, and prescribing of malt alcoholic beverages, long used medicinally by physicians, thus nullifying the right of the physician under existing law to prescribe alcohol by denying its use in this form; and whereas, up to this time, there had not been presented to Congress any scientific or authoritative exposition of the principles underlying the use of alcohol in medicine upon which to base these measures, "Therefore, be it resolved, that the Medical Society of the County of New York respectfully petition Congress to defer action on the amendment now demanded by the certain religious, lay, and political bodies until the medical profession has had an opportunity to pass upon this measure in a scientific session at the meeting of the American Medical Association soon to be held at Boston."

Factors in the Causation of Symptoms of Enteroptosis.—Dr. DUDLEY ROBERTS made this presentation, which consisted in a lantern-slide demonstration. From the standpoint of enteroptosis he divided individuals roughly into two types: (1) Those with short lungs, a wide costal angle, almost transverse stomach, and short, broad abdomen, and (2) the opposite type, with long lungs, a narrow costal angle, more or less ptosed stomach, and long abdomen. Both of these types might be normal functionally. The idea that corsets were responsible for enteroptosis in women had been discounted in recent years, for while women no longer wore corsets enteroptosis was still common. The impression that only thin people were enteroptotic was also a mistaken one, for many fat women had distinctly narrow costal angles and ptosed viscera. In some enteroptotic people the colon was low and there might be a long-loop sigmoid, and yet these organs might functionate well. It was possible that people of the broad-chested type might acquire enteroptosis by habits of relaxation and bad posture. Such sagging of the viscera was very apt to occur in those of sedentary habits. It was not so much a question of the position of the abdominal organs as of their musculature. Loss of muscle tone interfered with peristaltic activity and therefore favored stasis. In view of these facts the idea that everybody who had a stomach low in the abdomen should be operated upon was absurd. Dr. Roberts then discussed possible effects of the nervous mechanisms controlling the abdominal viscera and referred to the possible influence that the endocrine system might exert through the sympathetic nervous system. He thought it rather difficult to realize how some abdominal disturbances, as, for instance, an acute diarrhea, could be dependent upon the endocrine system. Briefly summed up, the factors concerned in the production of enteroptosis and its accompanying symptoms might be said to be: (1) General maldevelopment of the muscular system. (2) Faulty posture. (3) Psychoneurotic manifestations. (4) Imbalance of the nervous system, either vagotonic or sympatheticotonic, possibly associated with endocrine dysfunction. (5) Visceroptosis and atony. (6) Complicating pathology. Enteroptosis brought on by impairment of the muscular system might be due to overwork, worry, underfeeding, or wasting disease. Such cases were relieved by diet, rest, improvement in the general nutrition, gastric support, and sometimes pregnancy. It was evident that medical procedures were likewise applicable to those cases which were due to faulty posture and to endocrine dysfunction. In the presence of psychoneurotic manifestations it was often difficult to say whether these were a primary or a secondary factor. These patients frequently complained of right quadrant discomfort and were often not relieved either by general treatment or by appendectomy. Colonic stasis, Dr. Roberts was inclined to believe, was much less frequent than they had been accustomed to think. The group of enteroptoses due to adhesions, adventitious bands, membrane, etc., was a comparatively small one. It was extremely important that enteroptotic patients be studied with the idea that they were suffering from symptoms, not because the organs were low in the abdomen, but with the idea that something else was causing the symptoms.

The Recognition and Correction of Enteroptosis in Children.—Dr. CHARLES GILMORE KERLEY stated that as the result of a study of 91 cases of chronic gastrointestinal disturbance found to be due to mechanical agencies they had been able to draw certain definite conclusions. The symptom-complex in these patients was very much alike. They showed malnutrition, had persistent or recurrent gastrointestinal disorders, in which gastric retention was often the main factor in the causation of the disturbance. The habitually poor appetite in these children was due to the fact that the stomach did not empty itself before the next meal. In this connection Dr. Kerley brought out the point that in the feeding of children the forcing of large quantities of milk after giving solid food was a mistake often leading to dilatation of the stomach and retention. He had also noticed that almost all of these children had been treated for acidosis. In the dilated stomach there was defective muscular tone and hypermotility. In the vomiting child they had found that vomiting, whether recurrent, habitual (daily), or occasional, was associated with the ptosed stomach which was mechanically difficult of emptying and showed hypermotility or hypomotility with pylorospasm, the last being a frequent indirect factor in causing an emptying of the stomach through vomiting, the spasm apparently being due to causes operative elsewhere in the gastrointestinal tract, as dilatations and sacculations in the cecum, sigmoid, etc. The first step in the treatment of these patients with ptosed stomachs was a properly fitting support; other important factors in the treatment were rest after meals and allowing the stomach to empty itself before food was ingested. The great need of these children was proper nutrition, and how to bring this about was often a difficult problem. Dr Kerley emphasized strongly the fact that many cases of enteroptosis in adults had their origin in congenital defects or were due to causes operative in early life rather than to wearing corsets. Dr. Kerley illustrated his talk with lantern slides showing various forms of ptosed stomachs in children and other anomalies in various parts of the intestinal tract.

Medical Measures for the Relief of Enteroptosis.—Dr. ARTHUR F. CHACE discussed this phase of the subject.

He stated that Glenard's conception of enteroptosis was an essentially anatomical one. Since his time we had come more and more to think of this disease in terms of disordered function, and to consider its medical problems from the standpoint of disordered physiology and chemistry. Enteroptosis was accompanied by extreme retardation of peristalsis at certain points, such as the stomach, duodenum, the ileum, the cecum, and the flexures of the colon, resulting in localized stasis. The symptom-complex of enteroptosis had come to embrace gastric stasis, ileal stasis, cecal stasis, and colonic stasis. These conditions produced substantially the same subjective symptoms; the objective symptoms depended upon the part affected. In order to obtain relief of enteroptosis, it was necessary to go back of the anatomical defect and to ascertain the cause that had produced the condition of lack of muscular tone and nerve force. Invariably this cause lay in some fundamental disturbance in physiology. The displacement of the stomach or cecum had relatively little bearing upon the production of symptoms. The important question was "Does the organ function normally?" Before instituting any form of medical treatment, it was imperative to determine the etiological factor in a given case. A thorough search should be made to see if there were any lack of balance in the internal secretions. Oftentimes there was deficiency in the secretion of the suprarenal gland; sometimes there were evidences of vagotonia—disorders of the thyroid, pituitary, or adrenal secretion—and these cases must be thoroughly studied to see if any benefit might be derived from the use of glandular therapy. The prophylactic treatment should begin in childhood by giving attention to the general rules of hygiene and avoiding faulty posture and fatigue, and by supervision of the diet so as to prevent overloading of the stomach and constipation. In women particular care should be taken following childbirth, to induce the abdominal muscles to regain their normal tone by means of properly fitted belts and by exercise. In the general treatment in addition to glandular treatment, if such were necessary, subnutrition and toxemia must be overcome. It was necessary to correct the toxemia before one could expect the patient to assimilate sufficient nourishment to overcome the lowered nutrition. To this end stasis must be overcome regardless of its location. Saline catharsis must be resorted to at first, and sometimes good results had been obtained by flushing the entire tract by duodenal irrigations giving 500 c.c. of a 4 per cent. sodium sulphate solution directly into the duodenum through a duodenal tube daily. Where the stasis was more marked in the colon results might be obtained by high colonic irrigations, using normal saline in the average case, and a 3 per cent. solution of sodium bicarbonate where there was much mucus. It was unwise to continue irrigation more than a few days. Following irrigation the function of the bowel might be restored by giving retaining enemas of sweet oil at night and a diet which would make the contents of the bowel soft, bulky, and moist. This end might be attained by adding to the diet preparations of mineral oil, agar-agar, flax-seed compounded with agar-agar, emulsions of agar-agar and mineral oil, psyllium seeds, bran, fruit, and vegetables. At first it was necessary to have the vegetables very carefully prepared and administered in small amounts to avoid the formation of gas. As soon as the toxemia was broken up the stools became normal, and the urine free from indican, then an effort was made to have the patient gain in weight, by means of forced feeding, which accomplished two purposes—it increased the serum albumen and serum globulin content of the blood causing the body cells to be bathed in the most nutritious fluid possible, and, secondly, it caused a gain in weight, increasing the intraabdominal fat. This, in turn, raised the intraabdominal tension, forcing the organs up to more nearly their normal position. It was advisable to give small amounts of food often. By the addition of fats and carbohydrates to the diet the patient could be given one thousand to fifteen hundred calories more than the maintenance diet. In cases of nerve exhaustion it was wise to carry out a dietetic regime in bed. The patient should rest one hour after each meal with a warm, moist dressing over the abdomen. The foot of the bed should be elevated about 6 inches, and in severe cases of gastroptosis it was wise to have the patient lie on the right side to facilitate emptying of the stomach. In severe cases it might be necessary to give the stomach a complete rest of several days by feeding the patient through the abdominal tube. In order to establish normal tone in the atonic parts of the digestive tract systematic exercises were necessary. The most important ones were bending movements combined with deep breathing exercises, taken systematically and stopped short of fatigue. They might be supplemented by massage, particularly of the vibratory form, special attention being paid to the affected part. The general nerve tone should be improved by hydrotherapy—cold douches followed by vigorous rubs. Electricity and massage were very poor substitutes for exercise. Much attention must be paid to the restoration of normal muscular tone. In ambulatory cases, pending the development of the abdominal muscles some form of support was necessary. Relief was afforded by the application of adhesive plaster in such a way as to elevate the abdominal organs and to increase the intraabdominal tension. In women a properly fitted corset or belt, or a combination of the two, in which there was even support applied to the lower part of the abdomen and no downward pressure in the upper part of the abdomen, afforded relief, but should be regarded as a crutch to be used only temporarily, until the abdominal muscles could be properly developed, and in older patients in whom it was too late to have a proper muscular development. Iron, arsenic, and strychnine were valuable aids in treatment. At times they might be given advantageously hypodermically. In order to prevent recurrence patients should be warned against constipation, anemia, and allowing their muscles to become flabby. This necessitated careful attention to their diet and habits of exercise.

Surgical Problems Associated with Enteroptosis.—Dr. ALFRED S. TAYLOR made this contribution. He said he quite agreed with the opinion that mere position had relatively little to do with function and that operative procedures were contraindicated in enteroptosis that could be relieved by medical and hygienic measures. There was no reason why enteroptosis *per se* should cause disturbance of function. Dr. Taylor then spoke more particularly of his personal experience with some 70 cases of enteroptosis, many of them showing complicating factors. In a large number of these a relief of the complicating factor relieved the symptoms from which the patient was suffering. For instance, there might be a condition at the pylorus which, if relieved by an appropriate operative procedure, would relieve the symptoms. Dr. Taylor described various types of bands, membranes, and angulations, and referred to the description of these anomalies by Harvey in the *Annals of Surgery*, June, 1918. He explained the mechanism by which these acted to interfere with function. Sometimes if these bands and membranes were sufficiently long and flexible they caused no symptoms and no functional disturbance; in other cases they were responsible for the symptoms which could only be relieved permanently by dealing with their cause. Dr. Taylor said he was particularly interested in Dr. Kerley's presentation because his theory of the origin of these gastroenteroptoses was quite in keeping with the findings in the cases he had operated upon. In about 20 per cent. of this series of 70 cases there was an associated chronic appendicitis. The best means of differentiating between the cases due to adventitious bands and membranes and those having a physiological basis was by a study of the slides. In these cases symptoms were frequently relieved by a plastic operation. About 75 per cent. of the cases in his series had been received by appropriate operative interference.

Dr. C. WARD CRAMPTON expressed his appreciation of the comprehensive discussion of the subject in the foregoing papers. He distinguished four types of ptosis, namely, (1) visceral; (2) skeletal; (3) circulatory; (4) emotional—which usually occurred together. Three of these forms of ptoses were well known, but circulatory ptosis was not. It was a symptom of asthenia characterized by a failure of the systolic pressure to rise on assuming standing position and accompanied with an undue increase in pulse rate. With reference to the treatment of ptosis, exercise was

always considered of value, but various forms of exercise and their different uses and results were not so commonly recognized in practice. They were given as follows:

(1) *Abdominal exercises* for (*a*) strengthening, (*b*) increase in tone, and (*c*) shortening of the flat muscles of the abdomen. (2) *Abdominal massage* and automassage from a variety of movements. (3) *Cervical exercises* for strengthening, toning, and shortening the posterior muscles of the neck with a view to keeping the crevical spine straight and suspending the thorax. (4) *Dorsal exercises*, particularly for the deeper longitudinal dorsal muscles, avoiding contraction of the rhomboideii. (5) *Thoracic exercises* for the intercostal diaphragmatic development. (6) *Organic physiological exercises* for circulatory and general alimentary stimulation and improvement in metabolism. (7) *Recreation* for organic effect, time consumption, and correction of mental asthenia.

Dr. WILLIAM A. DOWNES said he knew of no subject which held so many pitfalls for the surgeon as enteroptosis. He agreed with Dr. Roberts and Dr. Taylor that the symptoms of which these patients complained were seldom due to the condition itself. It was his conclusion that enteroptosis uncomplicated was a medical and not a surgical disease. He had in the past employed the various "pexies," but he felt that with a few exceptions he had not been quite fair to the patient. In certain types of cases, as in obstruction at the terminal duodenum due to drag of the mesentery, by doing a duodeno-jejunostomy he had obtained some very gratifying results. If the cases were properly selected and there was a real mechanical difficulty one might then accomplish a great deal. Most of these patients were nervous, irritable people who were hard to treat and to handle, and unless one was absolutely certain that he was making a correct diagnosis it was a serious error to have them undergo a difficult and often an unnecessary operation. To advise operation with the idea that one might possibly find a band was not always a justifiable procedure. In many of his seventy cases Dr. Taylor said he had removed a pathological appendix; Dr. Downes wondered if that might not account for the good results. Dr. Downes asked Dr. Taylor how many cases in which he had found bands he had reoperated. It had been his experience in reoperating for conditions in the upper right quadrant, even where he had simply removed the gallbladder and there was no drainage, that adhesions had reformed out of all proportion to those present before the operation.

Dr. MAX EINHORN said that he had been interested in this subject for thirty years, and he was glad to say that he fully agreed with almost all the speakers tonight. Twenty-five years ago many physicians did not agree with him. Now views had changed, he was glad to say. Methods of diagnosis had changed, and since the advent of the *x*-ray anybody could see that enteroptosis was of very common occurrence. Dr. Einhorn called attention to the fact that in his first paper on this subject he had said that enteroptosis could exist in people who had no symptoms and that it was compatible with health, and his contention was that the reason we found disease so commonly associated with this condition was because enteroptotic people were easily upset, they were upset very much easier than normal persons. That was the reason why so many people of this type showed dyspepsia, hyperchlorhydria, achylia-gastrica, cholecystitis, etc. Returning to the subject of treatment, Dr. Einhorn said that formerly there were few who dared say this type of cases should not be treated surgically while now everyone agreed with regard to this point. The underlying principle of treatment in these cases was to put plenty of good food into the body, as many of these patients suffered from undernutrition. Now that everybody realized this better results on the treatment of enteroptosis could be expected. A comfortable support, while not absolutely necessary, was a great help, and exercise was also a very essential part of the treatment. There was no doubt that some enteroptotic people required surgery, but then there was some other factor present that could not be removed medically. One feature not brought out this evening was that sometimes patients suffered from dyspnea and in a number that difficulty was due to prolapse of the liver and sometimes of other organs, but principally of the liver.

The way to recognize that variety of dyspnea which could be easily cured was that while a man with asthma felt better when up and about these patients felt better when lying down and suffered from dyspnea when up and about.

Dr. DOUGAL BISSEL said his interest in this subject was chiefly surgical, and it was from this standpoint he proposed to discuss it. *First*, could the stomach be permanently fixed? *Second*, could it be fixed to advantage; relieving the symptoms of which the patient was compaining? *Third*, could the stomach be permanently fixed without sequelæ more disturbing than the original condition for which the operation was performed?

Could it be fixed? The answer to this question depended, first, upon the character of operation employed; second, upon the individual operator and the thoroughness with which one carried out the technique.

Could the stomach be fixed to advantage? The answer to this question was given by Dr. Roberts in the several patients whose *x*-rays before and after operation he had showed at this meeting, and in many other patients upon whom Dr. Bissel had successfully operated, some of whom were previously under the care of distinguished members within his hearing.

Could the stomach be permanently fixed without sequelæ, etc.? This question could also be answered in the affirmative. Though it had been his misfortune in a limited number of patients to fail to secure the full improvement desired, yet in no instance, so far as he had been able to ascertain, had the patient been left in a worse condition than before the operation. Failure in an individual case should not condemn operative procedure. Success in an individual case proved what could be done.

Dr. ROBERT T. MORRIS called attention to a point not brought out during the evening, namely, the frequent association of enteroptosis with other stigmata of degeneration, such as the high, arched palate, defects of various structures, etc., making it evident that enteroptosis was but a part of the general picture of degeneration. In regard to surgery in these cases, he said that during the last thirty-five years he had changed his mind many times. He had done all the "pexies" and had now reached the conclusion that they were mostly wrong. When the colon dropped because of a relaxation of the peritoneal supports it dragged upon the nephrocolic ligaments and pulled one or both kidneys out of Gerota's pouch. Operation in such a case was wrong, gained nothing permanently, and was not desirable. In some cases the kidney might make torsion of its vessels and nerves, and the ureter become angulated. The semilunar ganglia might be disturbed enough to give rise to gastric crises. In such a case operation upon other organs certainly did no good unless the kidney was fixed; also a ten minute operation for fixation of the kidney was sometimes desirable when the kidney had its own set of real symptoms. The "pexies" for the relief of gastroptosis were for the most part measures of the past. Following almost any "pexy," there might be a gain in weight and temporary well-being. If one wanted to report good results following enteroptosis operations he should report his operations very quickly.

Dr. ANTHONY BASSLER said that of course an enteroptotic kidney with Dietl's crises should be anchored. Dr. Roberts was right when he stated that no diagnosis of ptosis should be made on low position of the organs alone. If, however, there was peristaltic deficiency, errors of secretion, structure, makeup, or posture, causing functional disturbance or symptoms, then diagnosis of enteroptosis might be warranted. He thought Dr. Kerley's dictum of retention in children should be carried on through the adult ages because it was the one main characteristic in adult stomachs with ptosis trouble. One difficulty in this was the practice to employ the six-hour method of estimating retention, whereas *x*-ray men should use a four, four and one-half, or five-hour test, although not a few showed a retention of six hours. He believed that at least one-half the ptosis cases in adults had chronic toxic gut conditions, and the symptoms were very likely to return if this was not corrected. Dr. Bassler asserted that his position was somewhat different from that of Dr.

Chace in that he did not think it was necessary to clear up the gut condition first but to treat the ptosis first and handle the gut condition afterward. He thought a fair estimate would show that 31 per cent. of enteroptotic conditions had endocrine disturbance, 20 per cent. pathological conditions other than ptosis, and that 69 per cent. of all cases had a definite neurological condition. He had observed the results of seventy-nine operations for ptosis alone, not for associated conditions. These had been followed for over a year and but two were better. He believed, as Dr. Chace said, that this subject of ptosis was an individual matter; there were no general rules. On the average it took him four or five months to do any sort of a job on a ptosis case, a job that would stand strain and last. He did not think that any case that had a recurrence of symptoms could be considered to have been cured. One test, which to him was very interesting, was the one in those instances in which the results were good and one found that the stomach, not supported when the patient was in the erect position, rode higher than when the patient was in the prone position. He considered such a result as confirmatory of a real cure.

Dr. FENTON B. TURCK said the papers of the evening had covered the subject of enteroptosis very completely, so far as the textbook descriptions went, and they all said practically the same thing, namely, that enteroptosis was a metabolic disease, and they brought out the fact that one of the symptoms was fatigue—fatigue of the entire body as well of the gastrointestinal tract. But they did not go back of fatigue as a symptom and show how this fatigue was produced and how it affected the organism. The speaker's researches on the subject showed that fatigue had its inception in the cellular activities of the body, resulting in cell autolysis and the production of metabolites. He had further shown that this cellular autolysis was not due to microbic action, but was caused by the toxins of the tissues themselves. Dr. Kerley had done a beautiful piece of work in showing how enteroptosis frequently began in early life, and had shown that fatigue and disordered metabolism had a part in producing this condition, but the underlying cause had not been touched upon. Dr. Turck then referred to his experimental work on shock, in which he had shown that shock was due to tissue autolysis and the production of metabolites which were instrumental in producing gastric dilatation fatigue and dilatation. Foreign investigators had confirmed this finding and were agreed that shock was due to the metabolites of tissue poisoning. This having been proven, the logical treatment was by the injection of tissue extracts containing the specific antibodies for fatigue which could always be traced to tissue destruction. The reason that the young patients as well as the older ones suffered from atony and dilatation was not because of greater increase of the production of tissue extracts acting as toxins, but because there was frequently a diminished production of the normal resistance (the normal antitoxins), and no progress could be made in the treatment until these normal antibodies were supplied to the individual case showing this deficiency. Rest alone was not sufficient. What was needed was not drugs to palliate the symptoms, or surgery to tear out the fatigued organs, but to restore to the individuals their required normal antibodies, or what was popularly designated the normal "resistance." These normal antibodies directly neutralized the fatigue toxins which generated from the tissues. Dr. Turck had shown that atony and dilatation of the gastrointestinal tract did not occur by any means whatsoever until the tissue extracts were liberated from the tissues in excess of the normal antibodies present in the organism. Dr. Turck called attention to his method of toxin-antitoxin treatment with tissue extracts and the antitoxins produced by injecting animals (horses) with human metabolites, fatigue toxins, or tissue extract. This produced a curative serum which neutralizes the fatigue toxins. He preferred to call the tissue toxin "*Cystost*," and the antitoxin "Anti-Cystost."

Dr. A. S. TAYLOR, in closing the discussion, said that if the dictum were laid down not to operate unless one were sure of the diagnosis he would like to know how many surgical cases would be operated upon. In gallbladder cases if one had to be absolutely sure of the diagnosis very few gallbladders would be exposed. With increasing experience they were becoming able to make diagnoses with increasing accuracy. In his series of cases of enteroptosis accuracy of diagnosis had been fairly high. In fifty of these seventy cases the operation had been performed at periods ranging from two to seven years, and in about 75 per cent. the symptomatic cures were almost perfect.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE SURGICAL CLINICS OF NORTH AMERICA. February, 1921. Volume 1. Number 1. 259 pages with illustrations. Published by W. B. Saunders Company, Philadelphia.

THE PRINCIPLES OF IMMUNOLOGY. By HOWARD T. KARSNER, M.D. and ENRIQUE E. ECKER, M.D. 309 pages with illustrations. Published by J. B. Lippincott Company, Philadelphia.

THE HEALTH OF THE INDUSTRIAL WORKER. By EDGAR L. COLLIS, M.D. and MAJOR GREENWOOD, M.D. 450 pages with illustrations. Published by P. Blakiston's Son & Company, Philadelphia.

THE ORIGIN AND PROBLEM OF LIFE. By A. E. BAINES. 97 pages with illustrations. Published by E. P. Dutton & Company, New York.

GERMINATION IN ITS ELECTRICAL ASPECT. By A. E. BAINES. 185 pages with illustrations. Published by E. P. Dutton & Company, New York.

SIXTEENTH ANNUAL REPORT OF THE BOARD OF MANAGERS OF THE MANHATTAN STATE HOSPITAL TO THE STATE HOSPITAL COMMISSION FOR THE YEAR ENDING JUNE 30, 1920. 64 pages with illustrations. State Hospitals Press, Utica.

DIE BEDEUTUNG DER VERSCHIEDENARTIGEN STRAHLEN FUR DIE DIAGNOSE UND BEHANDLUNG DER TUBERKULOSE. Von Dr. RUBEN GASSUL. 72 Pages. Verlag von George Thieme, Leipzig.

DE L'ANAPHYLAXIE À L'IMMUNITÉ. By MAURICE ARTHUR. 361 Pages. Published by Masson et Cie. Paris.

VERÖFFENTLICHUNGEN der Robert Koch-Stiftung zur Bekämpfung der Tuberkulose. Ban 11 Heft 3. 195 Pages. Verlag von George Thieme, Leipzig.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints Volume XXXVI. 589 pages with illustrations. Published by the Rockefeller Institute for Medical Research, New York.

HUMAN HEREDITY, by CASPER L. REDFIELD. 107 Pages. Published by Heredity Publishing Company, Chicago.

RADIANT ENERGY AND THE OPHTHALMIC LENS. By FREDERICK BOOTH. 226 pages, with illustrations. Published by P. Blakiston's Son & Company, Philadelphia.

TREATISE ON FRACTURES. By JOHN B. ROBERTS, M.D., and JAMES A. KELLY, M.D. 755 pages with 1,081 illustrations. Published by J. B. Lippincott Company, Philadelphia.

FOUNDATIONS OF PSYCHIATRY. By WILLIAM A. WHITE, M.D. 136 Pages. Published by the Nervous and Mental Disease Publishing Company, New York.

THIRTY-SIXTH ANNUAL MEDICAL REPORT OF THE TRUDEAU SANATORIUM. 846 Pages.

KONSTITUTIONS AND VERERBUNGSPATHOLOGIE. Von HERMANN WERNER SIEMENS. 229 pages, with illustrations. Verlag von Julius Springer, Berlin.

BLOOD PICTURES. By CECIL PRICE-JONES, M.B. (Lond.). With 5 colored plates and 3 illustrations in the text. Second Edition. Published by William Wood & Company, New York.

A TEXT-BOOK OF PATHOLOGY. By ALFRED STENGEL, M.D., and HERBERT FOX, M.D. 1111 pages, with 509 illustrations. Price, $8.50. Published by W. B. Saunders Company, Philadelphia.

MEDICAL ELECTRICITY, RÖNTGEN RAYS, AND RADIUM. By SINCLAIR TOUSEY, M.D. 1337 pages, with 861 illustrations. Price, $10.00. Published by W. B. Saunders Company, Philadelphia.

Miscellany.

NEW BOOKS AND OLD.

IX.—Guerini's History of Dentistry.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

In 1909 the National Dental Association brought out through one of the larger publishers, Guerini's History of Dentistry. If your library has neglected this subject, lose no time in getting this valuable work, for the earlier essays on the history of dentistry are difficult or impossible to obtain. Perine, Dexter, and Cigrand are among the Americans who have devoted some time to this subject, while McManus in his introduction, mentions the work of Duval, Fitch, Carabelli, Snell, Linderer, and Harris among the foreign writers. In German, the Geist-Jacobi *Geschichte der Zahnheilkunde*, Tübingen 1896, and in French Lemerle's *Notice sur l'Histoire de l'Art Dentaire*, may be consulted but these works are scarcely available even in the larger libraries. The year after the appearance of Guerini's book, C. R. E. Koch's three volume History of Dental Surgery was published at Fort Wayne, Indiana. Another book of value, unfortunately out of print, is one issued some years ago by the S. S. White Dental Company. It is to be hoped that they will reprint it in the near future.

Among the earliest dental prescriptions are those in the Ebers Papyrus which is supposed to have been written in 1550 B. C., although the material for it must have existed from much earlier times. Caries and ulcerations are mentioned and various prescriptions given. There seems to be some doubt if the gold fillings occasionally reported in mummies were really put there during the life of the individual but there can be no doubt that at very early times, teeth from others persons were wired to adjacent ones to replace those lost. Guerini believes that the early Egyptians were as far advanced, if not farther, than any of the other earlier peoples who practiced dentistry.

When our author comes to the Hebrews he is able to give some interesting quotations, for while no dental medicine or surgery occurs in the Bible, there are numerous references to teeth, over fifty, but varying in the different translations. They go to show that while the early Hebrews probably suffered little from dental disease, they had nevertheless a proper appreciation of the value of good teeth. For example Guerini quotes the following:

> 23. Thou shalt give life for life.
> 24. Eye for eye, tootl for tooth, hand for hand, foot for foot.
> 25. Burning for burning, wound for wound, stripe for stripe.
> 26. And if a man smite the eye of his servant, or the eye of his maid, that it perish; he shall let him go free for his eye's sake.
> 27. And if he smite out his manservant's tooth or his maidservant's tooth; he shall let him go free for his tooth's sake. (Exodus—xxi: 23 to 27.)

The early Hebrews were not blind to the beauty and whiteness of the teeth: "Thy teeth are like a flock of sheep that are even shorn, which come up from the washing; whereof every one beara twins, and none is barren among them" (Song of Solomon iv:2). Numerous passages attest the fact that the soundness of the teeth was considered necessary to force and vigor. David says: "Arise, O Lord; save me, O my God: for thou hast smitten all mine enemies upon the cheek bone; thou hast broken the teeth of the ungodly" (Psalm iii:7), and in another place we find this sweetly pleasant prayer: "Break their teeth, O God, in their mouth" (Psalm lviii:6). Solomon uses broken or decayed teeth to symbolize weakness, "Confidence in an unfaithful man in time of trouble is like a broken tooth and a foot out of joint" (Proverbs xxv:19). The effect of acid substances on the teeth is alluded to several times, thus Solomon, "As vinegar to the teeth, and as smoke to the eyes, so is the sluggard to them that send him" (Proverbs x:26), and Jeremiah says, "In those days they shall say no more. The fathers have eaten a sour grape, and the children's teeth are set on edge. But every one shall die for his own iniquity; every man that eateth the sour grape, his teeth shall be set on edge" (Jeremiah xxxi:29 and 30).

We may pass over the consideration of dentistry among the Chinese except to call attention to the fact that acupuncture was a favored therapeutic measure in dental disorders. In this point Guerini says:

> There are twenty-six points of election upon which to carry out puncturing used as a remedy against toothache. There are also six other points of election for pains in the gums. One would naturally be disposed to believe that these points of election would be situated in proximity to the teeth. Instead, many of them are situated in distant parts of the body—for example, in the elbow, in the hands, the feet, the vertebral region, the coccyx, and so on. However, about half of them are to be found in the labial, maxillary, and periauricular regions. The puncturing of every point of election is almost always indicated for the cure of not only one but several, and, indeed, very often many maladies; for example, the puncture carried out on the point of election, *kin-tche*, situated at the outer extremity of the bend of the elbow, may be utilized in more than twenty-five morbid conditions; among which are pains in the arm, paralysis of the arm, edema of the whole body, excessive perspiring, vomiting, hematemesis, toothache, boils, gastralgia, hemiplegia, and even cholera!

Associated with puncturing is cauterization, as the site of the puncture is usually treated by means of the moxa. This is done with a kind of soft vegetable substance obtained from the leaves and dried tips of the artemisia. This is pressed into the shape of a small cone. A coin with a hole in it, as are the coins of China, is then pressed over the area to be treated. The cone of moxa is placed in the hole of the coin and then lighted. It burns slowly without excessive heat and produces a small circumscribed blister, without the production of much, if any, pain.

A short chapter is devoted to customs relating to the teeth such as dyeing them black or filling up the interdental spaces with gold leaf, or gilding the teeth, or coloring them red or other colors. The author might have gone on to a description of the present day custom of many Americans who seem to prefer gold teeth in place of the usual substitutes and to other vagaries including the actual setting of diamonds in the fillings.

Hippocrates gives numerous references to the development of teeth and to their diseases, but little is given concerning the care of the teeth. Guerini

has selected a large number of illustrative passages, only one of which we need quote as it shows as usual the remarkable clinical knowledge of the old father of medicine: "When a person has an ulcer of long duration on the margin of the tongue, one should examine the teeth on that side, to see if some one of them does not, by chance, present a sharp point." It took the medical profession many many centuries to come to a full realization of this advice, and even today there are undoubtedly large numbers of cancers that might have been avoided if irritation from dental deformities had been eliminated.

From the Greeks it is but a step to the dental art among the Etruscans and Guerini figures a number of interesting things such as dentures in terra-cotta, which the Etruscans used to present to their divinities as votive offerings. He also shows teeth crowns and appliances to support artificial teeth, after the manner of the bridge work of the present day and also appliances which were apparently designed to support some purely ornamental artificial substitute for the lost tooth.

The Romans were also familiar with dental disorders and large numbers of dental appliances and instructions have been preserved in many museums. Celsus gives extensive directions regarding carious teeth, fractures of the jaw, ulcers and the like. Guerini gives also a number of quotations from Pliny, full of directions for the use of various herbs and some other suggestions such as:

Apollonius writes that a very efficacious remedy for pains in the gums is to scratch them with the tooth of a man who has suffered a violent death. It is considered very beneficial for toothache to bite off a piece from wood which has been struck by lightning, and to touch the sick tooth with it; but whilst biting off the little piece of wood, it is necessary to keep both hands behind the back.

The Roman writer Martial speaks very clearly of artificial teeth which, judging from the quotations from his works, were designed so that they could be put on or off with great ease, which is good proof of the high state of dentistry in the Rome of his time, and Horace, in one of his satires, speaking of two old witches who had been put to flight, says:

You would have laughed to see those two old witches running toward town losing in their flight, Canidia her false teeth, Saginia her false hair.

Scribonius Largus, physician to the Emperor Claudius, whom he accompanied to England in the year 43, devotes a chapter of his book to the cure of toothache. Among other things he advises:

Violent toothache may be calmed in various ways, viz., with mouth washes, masticatories, fumigations, or by the direct application of fitting medicaments. It is beneficial to rinse the mouth frequently with a decoction of parietaria or of cypress berries, or to appiy to the tooth the root or the seeds of the hyoscyamus wrapped up in a cloth, and dipped from time to time in boiling water, or to chew the protulaca (purslane), or to keep for some time its juice in the mouth. Suitable also against toothache are fumigations made with the seeds of the hyoscyamus scattered on burning charcoal; these must be followed by rinsings of the mouth with hot water; in this way sometimes, as it were, small worms are expelled.

Tooth pastes and various washes and mixtures to be applied to carious or aching teeth were all well known in Rome long before the time of Galen. It was natural that Galen, writing as he did on everything, should have devoted a considerable attention to the teeth. Like many others of the early writers he was not inclined to recommend the extraction of teeth with forceps.

I have not space to quote the many interesting quotations collected by Guerini but the method of ridding one's self of toothache as suggested by Gnaeus Marcellus Empiricus, who lived in Bordeaux at the end of the fourth century may be cited:

Whilst in the open country, one must take a frog by the head, open its mouth and spit into it, then having begged the animal to take the toothache with it, must replace it on the ground and let it free. To remove loose teeth easily, it is necessary to keep in reserve some juice of black ivy mixed with a little green oil; in case of necessity, the nose of the patient must be anointed with it, and after having drawn a deep inspiration, he must put a little stone between his teeth, and stay with his mouth open, inclined a little forward, so as to let all the morbid humor flow out, which sometimes flows very abundantly and even may reach to three herminae. Having afterward rubbed the nose with pure oil, and washed the mouth with wine, the teeth will be free from every pain and may be very easily pulled out.

During the middle ages medicine moved to the East and with it dentistry, but the great Byzantine and Arabian physicians apparently added little to what was known before. The actual cantery was used and Abulcasis was apparently the first writer to consider cleaning the tartar off the teeth. Guerini quotes the following from the chapter "On the Scraping of the Teeth":

Sometimes on the surface of the teeth, both inside and outside, as well as under the gums, are deposited rough scales, of ugly appearance, and black, green, or yellow in color; thus corruption is communicated to the gums, and so the teeth are in process of time denuded. It is necessary for thee to lay the patient's head upon thy lap and to scrape the teeth and molars, on which are observed either true incrustations, or something similar to sand, and this until nothing more remains of such substances, and until also the dirty color of the teeth disappears, be it black, or green, or yellowish, or of any other color. If a first scraping is sufficient, so much the better; if not, thou shalt repeat it on the following day, or even on the third or fourth day, until the desired purpose is obtained. Thou must know, however, that the teeth need scrapers of various shapes and figures, on account of the very nature of this operation. In fact, the scalpel with which the teeth must be scraped on the inside is unlike that with which thou shalt scrape the outside; and that with which thou shalt scrape the interstices between the teeth shall likewise have another shape. Therefore, thou must have all this series of scalpels ready if so it pleases God.

Elevators were used in the extraction of teeth and also of splinters of teeth and bone, and crude dental saws of various shapes, as well as files, were frequently employed.

Dentistry, however, remained only a part of medicine practised by surgeons or by barbers or by persons in other occupations. Such writers in Europe as Guy de Chauliac included a considerable amount of material relating to dentistry and gave names to the various teeth.

It would take us too far afield to follow as Guerini does the various suggestions made by the writers in the thirteenth to the fifteenth centuries. With the revival of learning and the introduction of printing, contributions to dentistry, as to everything else, became more numerous. In Germany dentistry was in a crude state, practised by barbers, wander-

ing story tellers, magicians, even hangmen. These were generally forbidden to practice except at fairs but such prohibitions were perhaps broken as frequently as the Volstead Act is now.

One of the earliest books on dentistry was an anonymous work entitled *Zahnarcneybüchlein*, apparently first printed in 1530. This contains the description of cleaning carious teeth and filling the cavities with gold leaf. Another book of dental interest was written by Walter Hermann Ryff of Strassburg. His work was entitled "*Nuetzlicher Bericht, wie man die Augen und das Gesicht schaerfen und gesund erhalten, die Zaihne frisch und fest erhalten soll,*" or "Useful Instruction on the Way to Keep Healthy, to Strengthen and Reinvigorate the Eyes and the Sight. With Further Instruction on the Way of Keeping the Mouth Fresh, the Teeth Clean, and the Gums Firm." Ryff was the first to note the relation between disease of the teeth and the eyes.

Vesalius, Fallopius, Eustachius, and the other anatomists contributed much to the proper understanding of the development and the anatomy of the teeth, and Ambroise Paré brought the practice of dental surgery to the highest point that it had yet attained and figured a large number of dental instruments. I must refer the reader either to Guerini's abstracts or to the works of the great master himself for further details, but they are quite worth while looking up.

Additional works now began to be published with greater frequency, such as the work of the Spaniard, Francisco Martinez, who between fifty and fifty-seven published his "*Coloquio breve y compendioso sobre la materia de la dentadura y maravillosa obra de la boca, con muchos remedios y avisos necesarios, y la orden de curar y adreçar los dientes.*" "A brief colloquy and compendium on dentistry and the marvellous work of the mouth with many remedies and the necessary advice concerning the care and extraction of the teeth."

The second dental monograph in the German language was published at Frankfurt in 1576. It was the work of Adam Bodenstein von Carlstad. From this and others Guerini has gleaned sufficient to give one a pretty good idea of the state of dentistry in the sixteenth century. He also gives at some length, the story of the golden tooth, a curious myth which received quite as much attention as do similar things in our own day. In the sixteenth century there were distinct evidences that the dental science was to become separated from medicine and surgery and in the seventeenth century this becomes more marked, but still the dental contributions continued to be made by those celebrated in other lines. I can merely mention the work of Fabricius Hildanus, Johann Schultes, Nathaniel Highmore, and pass over a large number of other names, some well known and others scarcely ever seen in print. One gets a rather good idea of the thoroughness with which Guerini has gone over the early literature by the fact that he mentions the opinions of Walter Harris, a celebrated pediatrist of the latter part of the seventeenth century, whose life and writings I described at some length in a recent number of the Annals of Medical History.

The founder of modern dentistry was Pierre Fauchard. His celebrated work is entitled *Le Chirurgien Dentiste* (1728). Like all innovators, he had to suffer a great deal of envy and opposition.

About 1700 the dentists began to form a well defined class and in France examinations were necessary to be admitted to practice.

Guerini gives a very extensive account of Fauchard, who figured a large number of instruments which he devised, some of which are in use today with little or no alteration. Fauchard was a man of great ingenuity and originality. He not only did dental operations, made appliances to replace one or more missing teeth, but used various methods of filling cavities and was skilled in applying artificial crowns either to neighboring teeth or in the roots which he left. He even attempted to supply a complete denture but with rather indifferent success. He also manufactured artificial teeth and had them covered with enamel so as to resemble the natural object.

Guerini also gives some space to the well known contributions of John Hunter, "The Natural History of the Human Teeth," London, 1771, and "A Practical Treatise on the Diseases of the Teeth," London, 1778. These works and a few others bring the history of dentistry up to the end of the eighteenth century, where our author and we will leave it.

Psychoanalysis in France.—In the Bulletin of *Le Progrès Médical* for April 16, 1921, xlix, 16, is a notice of a Franco-Swiss translation of Freud's recent work on psychoanalysis. There is a preface by Claparède, devoted to Freud and his methods, in the course of which it is stated that the French have been the last to show an interest in the subject. The first announcement of the latter was received with hostility and a man like Pierre Janet, for example, does not seem to have grasped the inwardness of the subject matter. In all of the other countries the ideas of Freud have given an impetus to the study of psychology. In France he had for a long time but a single advance agent. Moricheau-Beauchant of Poitiers. Then others followed—Regis, Hesnard, Dupré, and Trepsat. Of the old psychologists Ribot alone showed himself more open to conviction than many of his juniors. But he adds that Paul Bourget, the novelist, has produced in Nemesis one of the most original psychological romances of the time, in which he introduces Freud's ideas. In Geneva a number of Franco-Swiss psychologists are Freudians, as Bovet, Morel, Flournoy, and de Saussure. Vodoz has applied psychoanalysis to the Song of Roland and to Victor Hugo's poem. But not all the Genevese are partisans of Freud, exceptions being Larguier des Bancels and Christin. The editor thinks that Claparède has exaggerated the ideas of ostracism and indifference of the French toward Freud. He shows that as far back as 1913 and 1914 there were favorable and even enthusiastic reviews in French periodicals and cites a dozen of them. It was only the abuse of the idea that was antagonized. A passage from Janet in 1919 is quoted as highly appreciative of Freud. When a man puts Freud in the class with Sir Isaac Newton and other men of genius, however, he must expect some dissent on the part of the public.

SURGERY AMONG UNCIVILIZED RACES.*

BY J. RAWSON PENNINGTON, M.D., F.A.C.S.,

CHICAGO.

CORRESPONDING MEMBER, ROYAL SOCIETY OF MEDICINE, LONDON (SURGICAL SECTION)

To do justice to this subject would require many hours, so all I can expect in a short period is to make a landing—as the airmen say—here and there. Moreover, I shall not touch on mutilations, such as cutting off a joint or joints of the fingers as a mark of mourning; or amputation of the nose, common in some tribes of our Indians, for punishment of unfaithful wives.

Commencing then with minor surgery: Bleeding was apparently common and widespread; thus the first Spanish voyagers to Yucatan found it used there to cure all sorts of diseases. Cupping was also widely practised, either by simple suction with the mouth, or where the hollow horns of buffaloes and other animals were to be had, these served as cupping glasses. In Bhutan, north of India, oral suction as well as an ox-horn was resorted to, according to Laufer.

Acupuncture is said to be over 46 centuries old in China, and for my purpose can be alluded to for a moment. There are a great many favorite sites for the procedure, and manikins are made to show such sites. One still extant, made by order of the reigning emperor in A. D., 1027, has no less than 367. (I understand a few more have been added in the long interval.) There are nine sorts of needles, each with its special indications, arrow-headed, round, blunt, and so on. The indications duly set forth in a Chinese book dated 1717 (Thomson, Olpp).

It is probable that the cataplasms and other applications to wounds, etc., may have had some feeble antiseptic properties which had been found out empirically. The homeopathic principle—"like cures like"—was put into effect by the Hopi Indians in Arizona. When dealing with an inflamed surface, the increased temperature was thought to be due to fire, hence to counteract the effect the surface was sprinkled with ashes, charcoal, or other substances resulting from the action of fire. (A somewhat analogous practice among their neighbors, the Zuñi Indians of New Mexico, will be referred to later.)

For closing small wounds a rude suture of thorns inserted through the edges was in vogue, and in some tribes of tropical America, where the ants are of large—even enormous—size they were held against the edges of the wound, and when these were grasped by reason of the well-known pugnacious tendencies of these insects, the body was twisted off, leaving the adherent head to hold the edges in apposition. I would ask here, is it possible the formic acid has any curative properties?

Several years back a few cases were reported showing the matter-of-fact way in which the ruder races look on surgical conditions. The first occurred in a Navajo halfbreed in New Mexico, aged 30. On April 18, he was wounded by a .45 calibre bullet, which struck him on outer side of left leg and passed in through popliteal space (Figs. 1, 2). Nothing whatever had been done to check hemorrhage, and a cloth saturated with turpentine bound around the wound was the only local dressing. As necrosis ensued the man whittled off the dead flesh from time to time. At length, on Sept. 6, he was first seen by a physician (F. E. Hinch), and found in reasonably good condition, and, considering his only food had been the coarse diet of the natives, was well nourished. From four inches below the patella, the limb was entirely denuded of flesh, the only covering to the bones were scattered areas here and there, particularly on the foot. Amputation through the lower thigh being performed, was promptly followed by recovery. At the operation the femoral artery was found to divide into the tibials much higher than usual.

Not long after, two somewhat similar cases were reported by Thurston, an English army surgeon in India. The patients were both Hindus, though it is decidedly unlikely they will ever learn of my including them among "uncivilized races." (Here, as in one or two other places, I have not stuck very closely to my text so far as the "uncivilized" portion of the topic is concerned.)

The first Hindu, a man of 40, some four months prior to admission had a febrile attack thought to be malarial. On the tenth day a burning sensation suddenly developed in the right leg, with severe pain shooting down the sciatic. For a few days the pain grew worse, then slowly subsided, and in a week or so after the leg trouble made its appearance, the fever ceased. A month later blisters developed and persisted for three weeks, when the leg became painful once more with considerable itching. Four weeks previous to entrance sloughs appeared over the heel, then extended up the leg, and the foot mummified. The man pulled off the sloughs as they separated, until the condition as seen in picture was almost an exact duplicate of the halfbreed save for the different side of body. A successful thigh amputation was performed. No history of syphilis and no albuminuria, but the cardiac sounds were

*Read before Chicago Academy of Medicine, February 23, 1921.

weak, and the reporter believes the condition was due to embolism from a thrombus which formed in a weak heart during the febrile attack.

The second man, aged 50, entered hospital September 12. In the previous January, anesthesia of the finger tips made its appearance, then extended up about midway of forearm. In a couple of weeks a bleb between the thumb and index formed; this ulcerated, and the soft parts began sloughing off until only the bones were left. Late in April, after formation of the line of demarcation, the soft parts came away, then while the man was applying a native remedy of tree leaves, the bones too dropped off, after which the fever ceased. There was a specific history some 30 years previous, and at amputation through the elbow, the arteries proved to be thrombosed. Post-operative pneumonia delayed recovery.

Judging by the many bone-specimens, ancient and modern, from savages in all corners of the globe, which show fractures united with little or no deformity it is probable some rude support or splint had been applied. Neuburger believes the methods used for repair of broken weapons served in primitive times as a pattern for the treatment of fractures. The last survivor of the black inhabitants of Tasmania, died in 1876. In common with their neighbors to the North, the Australian blacks, they are generally regarded as the lowest in intellect of all humanity, yet they were in the habit of mashing up certain tree leaves there which became plastered together, and acted as a clumsy sort of splint. However, Dr. Hrdlicka, from his extensive observations among our own Indians, believes fractures and diseases of bone are less common among them than in the white race.

Several years ago, G. Elliot Smith, at that time professor of anatomy in the Egyptian Government School of Medicine, described what he appropriately terms "the most ancient splints." They were discovered in some rock-cut tombs of the 5th dynasty. Now there is great diversity of opinion among Egyptologists as to the approximate date of the ancient dynasties. One estimate puts this 5th one at B. C. 3500, another at 2625 B. C., but Smith observes that even taking the lowest estimate it makes the splints over 4500 years old.

The first set was on a girl of about fourteen years, with a compound fracture of the right femur about midway of the shaft. A piece of bone, two inches long and one-half inch wide, had been detached from the back of the shaft at the seat of fracture. Four splints had been applied, passing from just above the fracture to a point well below the knee. Each splint consisted of a slender piece of wood, sawn or roughly shaped with an adze, but not planed; these were then wrapped up by a carefully-applied linen bandage before being fixed to the limb. The splints were kept in position by two bandages, each tied in a reef knot, one above, the other below the knee. A large pad of linen just below the fracture was discolored by a rust-like stain, which on analysis yielded iron and was evidently produced by blood. Death apparently was not long delayed, for there is no evidence of any inflammatory or reparative action.

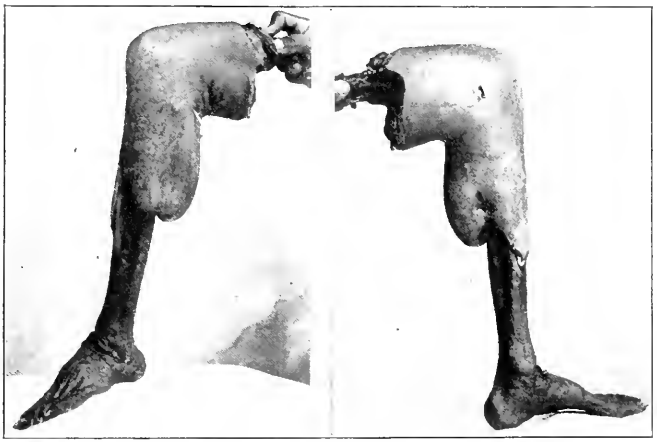

Fig. 1.—Navajo: wound of entrance. Fig. 2.—Navajo, wound of exit.

The Professor points out that a glance makes it obvious these splints must have been utterly useless as a support to the broken femur, or as a check to shortening. The only purpose could have been to fix the knee joint, thus ensuring some degree of rest to the limb. As might have been anticipated from a study of such splints, Smith's examination of a large series of ununited fractures of the femur from ancient tombs in Egypt, shows, as a rule, considerable shortening, displacement of fragments, as well as exuberant callus.

In the second set, a compound fracture of both bones of the left forearm, just about the middle of the shafts, had been cared for. The splint in this instance was of different construction, being made up of a complete tube of rough bark—thought to be acacia—with a bundle of straw or coarse grass. Again the injury was quickly fatal apparently, for there is no evidence whatsoever of any repair. In this case the bark had a natural curve which must

have adapted itself accurately to the contour of the limb.

The splints of the second case, writes Smith, present a marked contrast as to effective support, compared with the ones of the femur, and in over 100 examples of ancient healed fractures of the forearm studied by him, the results were excellent, many must have been compound, yet only one shows any signs of suppuration. This type of fracture, that is to say of both bones, has always been excessively common in Egypt from the earliest known prehistoric times to the present, and due to the custom of fencing with a heavy stick about five feet long, for both amusement and as a means of attack.

The intense conservatism of the Oriental is shown by the fact that shortly before Smith described a set of splints, found in a burial of the 7th century, A. D., similar to those just mentioned for the femur. Other instances of this conservatism were reported to him by an English army surgeon, and by his demonstrator of anatomy, an Egyptian native.

In 1903, the former accompanied some troops to Abyssinia, and among the patients who flocked to him for treatment there was a man with a broken forearm, equipped with splints exactly like those from Egypt 4500 years before. Smith's demonstrator informed him the use of such splints was still widely resorted to, though rapidly disappearing, owing to the increasing number of native medical men trained at Cairo by Western methods. In most villages the old women who act as bonesetters make a sort of mat with the stems of leaves from the date palm, which are laid side by side, and the limb is wrapped in them similar to the method in the second case above.

Among many other interesting observations, Smith alludes to a fractured patella set with splints, from a grave of the 7th century of our era. He also refers to a ludicrous affair showing the respect with which the remains of defunct royalty were regarded. The tomb of King Siptah of the 19th dynasty had been plundered, and during the despoilment the mummy had been stripped of its interminably long bandages and the right forearm fractured. Long, long after his death, the priests of the 21st dynasty had piously set the limb with splints and rewrapped the body.

Circumcision probably had its start in Egypt, and borrowed thence by the ancient Hebrews has become of well-nigh universal distribution. Among the Masai of Southeast Africa, the prepuce is not cut off, but divided and allowed to hang down, making a second glans penis as it were. The theory that circumcision began in warm climates as a hygienic measure, is severely jolted when we find it practised among the Loucheux Indians of Northern British Columbia, and the Dogribs further to the East, where, as the saying is, "it is six months winter, and six months late in the fall."

An extraordinary procedure is that of subincision found among the Australian blacks, and called in their jargon the "mika." This is an external urethrotomy, and another extraordinary feature is that members of our profession living on the spot do not agree as to the real purpose of the operation.

Stirling, for example, writes that subincision among the tribes visited by him is attended by much less ceremonial observance than in circumcision. "No reason," he adds, "can be elicited for either operation, save that it was done by their fathers and forefathers. I can find no support whatever that the specific object of subincision is to check procreation, as is so often alleged, though doubtless it may act in this direction . . . I heard of well authenticated instances of three, four, and even five in a family that were the offspring of subincised males."

On the other hand, Garson deriving his information from a Mr. Purcell, starts out with a definition of a mika as "a man upon whom artificial hypospadias has been practised for the purpose of preventing him having any family." Three types of this operation are met with: (1) The natives of W. Australia content themselves with making a small incision immediately in front of the scrotum and through the urethra. (2) In other portions (Diamantin River, etc.), the urethra being divided in front of the scrotum and again just short of the glans, is dissected out after additional grooves are cut along each side of canal. (3) The plan generally adopted is to place a narrow piece of wood along the dorsum of the penis, first beating the organ till it is benumbed. After the wood is in place, the skin is drawn back over it and a flint knife inserted into the meatus divides the canal back to scrotum. The operation finished, the organ is bandaged against abdomen, and if excessive inflammation occurs during the process of healing, dressings are applied either of some native clay, or crushed leaves of the eucalyptus tree. There seems to be no mortality.

"These operations are performed on youths at the age of 18 years and only upon a certain number of them, namely those who prove themselves indolent and the least useful members of their tribes."

Of these conflicting accounts it seems to me more credibility attaches to the one by Garson's informant; he had lived among the natives for a quarter-century, while Stirling made only two trips into Central Australia.

I now propose to discuss "trephining" so-called, at considerable length, both because the evidences of it are found in the New, as well as the Old World, and because it is the most serious operation I know of among the uncivilized races, with the exception of the cesarean section, from Uganda, Central Africa, reported by Felkin, the Scotch medical missionary in 1878.

The first example of prehistoric trephining was found in Peru in 1866, by our own Squier. In the left side of the frontal bone was a square opening, .58 by .70 inch. This was evidently done by a saw as shown by the four linear grooves. Now, with the exception of the precious metals, the Incas who inhabited ancient Peru, were only acquainted with copper, so the saw must have been of this metal, with a small amount of tin added which gave a cutting edge almost as hard as steel.

(A digression may be permitted here to the effect that long after iron had become the principal metal of everyday use in Europe, the majority of surgical instruments were still made of bronze. In looking over Vulpes' book showing the instruments discovered in the "Surgeon's House" at Pompeii in 1819, I was naturally much interested to find depicted a rectal speculum. The instrument fashioned about eighteen and one-half centuries ago is the same to all intents and purposes as the one from a surgical

instrument maker's catalogue of the present day [Fig. 3].)

Squier's specimen was brought to France, and excited much interest. Nélaton, the famous surgeon of that time, after examination thought the subject

FIG. 3.—Rectal specula: Pompeian to the left; one of the present day to the right.

had survived a fortnight. In a few years (1873) specimens were found in France itself, and since then in Belgium, Austria, Bohemia, Poland, Russia, Italy, Portugal, and the Canary Islands. On our side of the ocean, they occur in Bolivia, as well as the original site, but with the exception of some from Mexico, no further North (Lumholtz).

In some cases the individual survived as shown by the smooth edges of the opening, in others no trace of repair can be found. Some crania carrying double trephine holes, one made before death as proved by the smoothed-off apertures, while the other is post-mortem, or else the individual succumbed from the effects of the last operation, for no traces of repair are to be found. During our World's Fair, in Chicago, Dr. A. M. Muñiz, formerly surgeon-general of the Peruvian army, exhibited a remarkable series of these trephined skulls; of 1000 crania collected during several years, some 19 were trephined. In six instances the operation was evidently done for serious wounds, while in the remaining 13, there were traces of 18 different interventions, but not rendered necessary by trauma. Moreover, there were two specimens of double—and one of triple—trephining; the last specially interesting since all of the openings show traces of healing. One or two with four openings have been recorded from Europe.

The operation as shown by the crania was done in both sexes, and on children as well as adults and the aged. In some of the adults trephining was evidently done during infancy, for the intact side of the skull is better developed, and has encroached on the side with the opening. Most of the holes were made in the parietal bones, and the shape is elliptical, as a rule, the long axis measuring 1, 1½ or 2 inches. (In one specimen with a double hole, the sizes were 57 by 42, and 44 by 42 millimetres respectively.) But in the specimen with the silver plate found by Muñiz, the opening averaged an inch wide, and fully 4 inches long. Apparently the opening was always made through the hairy scalp.

As regards the modus operandi, the aperture was made by sawing or by scraping (Fig. 4), occasionally by combining these methods, and in some instances by cutting part way through and then breaking off the piece. Fortunately, some specimens have the marks left by the prehistoric operator, and give a clue to the probable workmanship. An example of this from a burial cave in France was carefully examined by the late Prof. Topinard, and he concluded the stone knife was grasped with the cutting edge at right angles to the skull, being brought in a circular manner and to the outer side, the knife slipped scoring the surface. Nothing daunted, the operator continued, the knife slipping frequently, especially as the incision was brought forward. When three-quarters of the incision to the outer side and behind were judged to be deep enough, the position of the hand and instrument was evidently changed, at first cutting obliquely forward from behind and from within out, then longitudinally from behind forward. The professor believes this longitudinal movement was the most difficult, since the edges are not clean cut, but rough. It is interesting to note also that most of the operation was done after death, for but a small extent had healed.

Several men have experimented with the actual tools of the stone age. Paul Broca, for example, in a puppy of 2 months, succeeded in laying bare the dura in 8 minutes and 15 seconds. Another investigator, once the soft parts in a dog were reflected, mapped out an elliptical opening, then scratched a furrow, slowly deepening this until the internal table was almost severed. With a piece of hard wood or bone as a lever, the fragment was forced off without producing any injury to the dura. The total time was 20 minutes and the dog suffered no ill-effects.

Muller, still another French observer, took a series of 11 human crania, scraping through in 4, and in the rest cutting out a round piece. Much more time was required to remove the circular fragment, over an hour, and in an unusually thick specimen just 5 minutes less than 2 hours. He discovered also it was more expeditious to map out a polygon first, next round off the angles, than to begin with a circle or an oval. Scraping was comparatively

FIG. 4.—Trephined skull (France); beveling probably done by scraping.

rapid, only 33 minutes elapsing before rasped through, again without injuring the dura.

Man must have been on the globe for a long time before he became expert enough to essay this operation. The relics and utensils found with such trephined skulls are all of the neolithic or polished-

stone era; I think none of the first stone age (the chipped-stone one) have been found associated. In fact of the three stages into which the polished-stone era is divided, these skulls are found only in the latest. Now from the standpoint of the mechanic arts considerable progress is in evidence, dwellings erected for security on piles driven into the lakes, and accessible from the shore only by an easily-defended causeway, or totally isolated and approachable by boats. These old-timers also had fishnets, ornamented pottery, and rude stone monuments. Nevertheless, a few skulls have been discovered dating from the bronze age, which immediately followed that of polished stone, and even the commencement of the iron age. To be sure as we shall find shortly, the trephining operation has survived here and there to our own time.

To assign an exact date to the relics of the stone age is decidedly conjectural. When dealing with these early times authors are prone to be generous, yes, extravagant, with their years Thus the elder Mortillet, a great authority in his time, placed the beginning of the polished stone age at 228,000 years ago, others put it at 30,000. The most modest conjecture I remember is 15,000 years ago. Suppose, however, that being in this year of grace 1921, we put it only as far previous to the Christian era, we have, it seems to me, a very respectable antiquity. What then was the reason for this far-off major operation? Was it therapeutic or thaumaturgic; or both or neither?

Several French authors assert the object was therapeutic. Some specimens have exostoses on the inner surface, they believe such bony outgrowths set up irritation of the cerebral cortex, and to relieve this focal irritation the skull was opened over the motor (or Rolandic) area. Other authors, also French, hence with the vivid imagination of our Gallic allies, believed they found evidence that there had been osteitis and similar bone lesions, therefore the diseased area had been removed for curative purposes. One of the latest of these, Canu, observes that the parietal bone of the left side was not operated on so often as its fellow, but he adduces no evidence why the exostoses or the rarifying osteitis should prefer this side. We know the whole vault of the cranium is nearly the same thickness, about 1/5 inch on the average, and it is quite likely that experience, that great teacher, had shown the parietal area was both convenient for access, as well as thin.

In some specimens traces of a fracture are to be seen at or near the opening, but there is no way to tell if this took place during the removal of the fragment, or whether the operation was done to treat the fracture. I should, of course, incline to the former view.

Lucas-Championnière, the celebrated Paris surgeon, interested himself for many years in this subject, and if I remember correctly it was while reading his last paper at the Academy of Medicine, that he was seized with his fatal apoplexy. In this communication he says in his opinion the prehistoric trephining is analogous to our decompression operations! This may be so, as a writer in this country observes, but it appears like stretching one's imagination unduly to believe that a savage, scantily clad in the skins of wild beasts, who lived in a cave, and ate his grandfather or his mother-in-law when food ran short, could know aught concerning the niceties of cerebral localization.

It seems to me the majority of anthropologists agree that such trephining was carried out for thaumaturgic purposes. The uncivilized races have generally looked on idiots, epileptics, or the insane, as supernatural beings. Witness Aaron Burr's travel alone through the hostile Indian tribes from the Mississippi to Virginia, early in 1807, from which he emerged unharmed owing to his being regarded by them as insane, therefore, under protection of the Great Spirit. Hence, as the early man may have reasoned, the wonderful properties could be transmitted by the bone fragments from individuals who had undergone trephining even after their death.

Accordingly, we find such amulets or "*rondelles*" as they are termed by the French, buried with persons whose own skulls are intact. As a matter of fact, they were counterfeited (Canu) in staghorn and even pottery by the John Alexander Dowies and Mary Baker Eddys of that epoch. Since pieces with only a portion of the healed area are common in the burial places, it seems they were regarded as equally powerful. Moreover, the "*rondelles*" have been met with having holes through them or notched on the edges so they could be fastened to the skins which served as clothing such as it was, and acting as ornaments as well. A curious discovery was made a few years since, the skull of an adult in which a piece, about 3⅓ by 1½ inches had been removed from the parietal, then replaced and had grown firmly in position. An early, yes! *very* early example of our practice of "replacing the trephine button." (Of course, where the aperture was scraped through, the bone would be reduced to powder, and none left to serve as amulets.)

About the beginning of this century a mummy was exhumed in Bolivia, in which a large flap of scalp had been raised from the occipital bone of the right side, no opening was made, however, as the bone was probably too thick. Hence another flap was raised also on the right side, and then a large aperture was made through parietal and frontal bones; through this the brain was removed and the cranial cavity stuffed with a mass of resin and other vegetable substances which was found still in place (Lehmann-Nitsche). This interesting circumstance recalls the method in use by the embalmers of ancient Egypt, that of breaking through the cribriform plate of the ethmoid, next extracting the brain through the nasal passages.

The South Sea islanders when first visited by white men were frequently in the habit of performing trephining by scraping with a flint tool, or with glass after they came in contact with Europeans. The aperture was then carefully closed with a piece of cocoanut shell, the precursor of our modern Cargile membrane, etc. Anybody who has ever seen a war club from these islands studded with jagged flakes of obsidian or shark's teeth, will readily believe there must have been many occasions for the exercise of their art by the primitive surgeons of the countries.

The Kabyles of Algeria, were another tribe who continued this practice until recent times; for that matter, so far as I know, they may keep it up even to this day. They used a rude sort of bone-drill, making several perforations, then connected the

openings by a cut made with an equally rude saw. In spite of the clumsy tools, the mortality was not high seemingly. One traveler encountered several men who had survived half a dozen operations at different times for various injuries. What an admirable piece of evidence for the healing power of Nature!

Mention of the cocoanut shell reminds me that one of the skulls collected by Dr. Muñiz, the one with the 4-inch opening had the hole covered in by a silver plate. This was still in place inside the wrappings and it had been fitted there so long there had been some absorption of the bone along the edges of the plate, proving the young adult had survived. The size of the opening is so great that the discoverer suggests several operations had been done in succession.

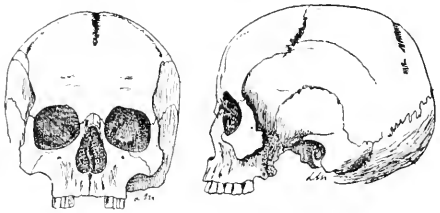

Fig. 5.—Skull showing the T-sincipital (France).

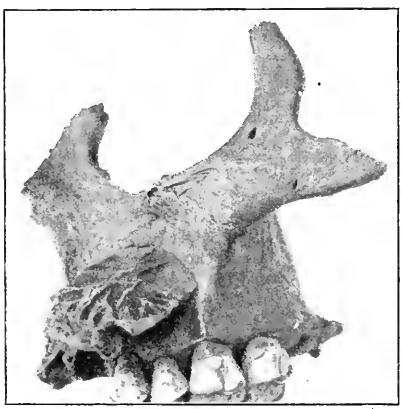

Fig. 6.—Maxilla of Indian (supposed to be of the mound-builders) with flint arrowhead embedded.

So much for trephining, I now turn to a queer mutilation, originating in this same polished-stone age, though to call it a "surgical" operation may be an unwarranted use of the term: This was described in 1895 by Manouvrier as the "*T-sincipital.*" As connoted by the name it is found on the vertex, always occupying the same position, and invariably of the same shape. The stem of the T starts in the midline, somewhat in front of the coronal suture, crosses it and continues some distance along the sagittal suture, where it is joined by the cross-piece of the T, extending down on each side about as far as the parietal eminence (Fig. 5). All the crania with this strange grooving on them which Manouvrier found were of females, though the ages differed considerably; he also calls attention to the fact that the lines follow these along which the hair is parted.

While barely perceptible in some skulls, the groove is deep in others. The deepest one from an aged subject, extended down $\frac{1}{8}$ inch laying bare the diploe, either from the wound itself or the resulting suppuration. On the other hand, the groove in the various specimens was not continuous, but invariably interrupted. Manouvrier believes this is important as proving the incision in the scalp was also interrupted, so as to leave bridges of intact skin. Another curious finding of his was that the ends of the branches of the T were very prominent, and as they always end in the same spot, even if the groove is not very prominent or is interrupted, the ends will be found in the usual places.

Our author could assign no reason for this strange scoring of the brain-box, but in the discussion something was said about the magic properties of the Greek T, or *tau*. Heavens and earth! the idea of such savages knowing anything about letters hundreds, maybe thousands, of years before the Greeks and their alphabet.

Reference has also been made (by Laloy) to Virchow's statement that during his youth in Pomerania, the insane were treated by applying antimony ointment to the head. Occasionally the ointment was left on too long, when great destruction of bone resulted, sometimes a perforation. Two specimens in the Anatomic Museum of Berlin, he said, were typical examples, the perforation in one being 1.8 by 1.6 inches, and in the other 1.8 by 4.5. It is hardly likely though, that our friends, the cave-dwellers, were acquainted with the destructive effects of Stibium. Another reference was to the prevalent custom in Central Asia of burning young children above the ears and along the vertex to ward off disease of the head (Zaborowski).

All the specimens found by Manouvrier were from an area to the Northwest of Paris, and somewhat limited in extent. But after his paper was published, it turned out that the same practice had been described by an English missionary only 21 years previous from the Loyalty Islands in the Pacific. Another instance, if any were needed, of the tendency of the human mind—even if of low development—to run in the same channels, though separated by incalculable ages.

The trephining of the Stone Age must necessarily have been done with pieces of flint—or some similar stone. On the tombs of ancient Egypt, the date about 2000 B. C., circumcision is shown as being done with flint or—at least—stone knives. You remember that a year or so ago, the surgeons in the hospital at Varna, Bulgaria, being without instruments improvised some cutting ones of flint knives. History repeats itself sure enough!

We owe many drugs to the savage—or uncivilized—races. I need only mention cinchona, hydrastis, jalap, koussoo, quassia and sarsaparilla; but we are not, I believe, indebted to them for any advances in surgery.

Medicine and surgery among such races are inextricably bound up with evil spirits, witchcraft and so on. Knowing nothing of etiology every sickness and death is caused by some magic, sorcery, etc. A striking example of this belief I borrow

from the account given several years back by the late Frank Hamilton Cushing: This well-known ethnologist lived for a long time among the Zuñi Indians of New Mexico; in fact he was a member of the tribe, having been initiated into the Macaw clan. He saw a man who had been thrown from his horse several months before, sustaining a contusion of the foot. At the time the operation was performed, the foot, together with the lower part of the leg, was swollen, to such an extent the skin was shining, except at the site of the original injury, where—to adopt Mr. Cushing's language—"a malignant and putrid sore" had developed. The medicinemen who were called in decided some of the muscles of the foot were dead or dying from the effects of the violence due to the fall, and were turning into worms. Operation was decided upon.

The outfit consisted of some sharp, thin flakes from the bottom of a glass bottle, and others of the volcanic glass (obsidian) so common there. These flakes were inserted into the split ends of pieces of cedar boughs to serve as scalpels. In addition there were provided willow bark, some bitter yellow roots, shredded cedar bark, scrapings from buckskin and old soft rags, lastly a bowl of fresh water, and another with infusion of willow bark. A T-shaped incision being made, the diseased tissue was

FIG. 7.—Lumbar vertebra with embedded flint arrowhead; from a burial cave in France

cut away by the glass—and obsidian—lancets, until the periosteum was laid bare. This as well was found discolored and inflamed, and was scraped away until the discolored portion was removed. The chief surgeon, as it were, filled his mouth several times with the willow bark infusion, and sprayed it over the field, after which the wound was dried. The incisions were next filled with gum from the piñon pine, finally bandaged up with strips of the rags. For the after-treatment, this comprised dressing the wound every day and dieting. The man was placed on "the freshest possible corn foods, and was for the first four days deprived of salt and all flesh food, and was thereafter until cured, for he recovered with amazing rapidity, denied all meat containing fat and other non-muscular tissue, since these as well as old seeds are supposed to be of themselves peculiarly liable to worm turning."

Mr. Cushing observes that while all the steps seem to have been conducted in strict accordance with modern surgical ideas, in reality they were a combination of empirical with thaumaturgic methods: The Zuñis believe that "good, fresh blood is the source of new flesh, and that water is the first source of the new blood of life itself, therefore, since the willow never lives apart from the springs or other continuous sources of water, it must contain within its roots the very source of life. An infusion of its roots and bark becomes brightly red," hence its use. The piñon gum is fine-feeding, therefore, purifying and maturing, while the yellow root is cooling and hardening, so their use is appropriate. Deep-seated worms must be the cause of the pain, hence, these must be got rid of to prevent their undue multiplication, which if not checked would cause death in time.

The Tibetans, according to Laufer, believe in lucky and unlucky days on which operations are to be performed.

I wish to state that the several pictures to be passed around are duly explained by their labels. The fragment of skull with the arrowhead embedded in it (Fig. 6), unfortunately has no history, even its locality is unknown. Evidently the wound was not fatal, though it may be the unfortunate victim was wounded sufficiently, possibly knocked down, to enable his antagonists to come up and despatch him. Or, he may also have been wounded in the chest or abdomen at the same time, as in the specimen in one of the pictures (Fig. 7).

In conclusion it becomes my pleasant duty to acknowledge my obligations to Dr. Berthold Laufer, Curator of Anthropology at the Field Museum of Natural History, for the loan of several German essays on Tibetan and Chinese medicine.

MEDIASTINAL SARCOMA.

WITH REPORT OF THREE CASES.

By REX DUNCAN, M.D.,

LOS ANGELES, CALIF.

MEDICAL DIRECTOR OF THE RADIUM AND ONCOLOGIC INSTITUTE, LOS ANGELES; CONSULTANT IN RADIUM THERAPY AND MALIGNANT DISEASES IN THE ORTHOPEDIC HOSPITAL-SCHOOL, LOS ANGELES; CHIEF OF THE DIAGNOSTIC GROUP FOR NEOPLASTIC DISEASES, LOS ANGELES COUNTY HOSPITAL.

THE purpose of this paper is to render a preliminary report of three cases of mediastinal sarcoma treated with radium. It may be permissible, however, to refer briefly to the frequency with which this disease occurs, and call attention to certain points incident to the diagnosis.

C. T. Herbert, in an exhaustive monogram covering the pathological anatomy of mediastinal sarcoma, reports the disease to have occurred in one in every 292 cases in the Victoria Park Hospital (a special institution for diseases of the chest), during the years 1908 to 1917, while in the period between December, 1915, and September, 1916, seven cases were found in 571 admissions. These figures include cases only on which a postmortem was made.

Though rather uncommon, this disease is of sufficient frequency to warrant a more thorough study and an earlier diagnosis, when treatment can be of most value.

Differential diagnosis should be made from aortic aneurysm, one of the most frequent of mediastinal tumors, Hodgkin's disease, tuberculosis, and syphilis. Primary may be differentiated from secondary tumors by a thorough examination, excluding the existence of malignancy elsewhere than in the chest. Benign tumors are quite rare and may exist for years with mild or no symptoms. They progress slowly, while malignant tumors advance more rapidly, death usually occurring in untreated cases in less than one year.

Examination with a laryngoscope and the esophagoscope, should be made to exclude laryngeal and esophageal tumors.

Primary mediastinal sarcoma arises in the lymphatic glandular structure of thorax and may attain considerable size before involvement of the adjacent structures occurs. Beginning in the glands, the new growth enlarges either by extension along the lymphatics to neighboring glands or by breaking through the capsule and invading the surrounding connective tissue, forming an irregular tumor which increases in size in the direction of least resistance. The growth may extend upward beneath the clavicles into the triangles of the neck or down around the large vessels and bronchi, without at first infiltrating these structures. Downward extension may displace the heart forward and to the left. Metastatic tumors may follow a course similar to primary growth.

Diagnosis can be made from the symptoms, physical findings, and the roentgenographic and fluoroscopic findings which are of the greatest value. The earlier symptoms are due chiefly to pressure varying somewhat with the location of the tumor. Dyspnea was the first and most prominent symptom in each of my cases. Pain is present, its character and acuteness depending upon the location of the tumor. Cough resulting from pressure on the respiratory apparatus was also an early symptom in each case, and hoarseness was present in two cases. Hemoptysis occurred in two cases. Loss of weight occurred in all cases. Cyanosis and venous dilation, particularly of the veins of the face, neck, and chest, and edema of the face constitute a prominent group of symptoms present in each of my cases.

Treatment.—Until recent years the treatment of these cases has been considered hopeless. Surgery has in a few cases afforded temporary relief of pressure symptoms but no cures. *X*-ray therapy has afforded little if any more success. The first, and by far the most encouraging results, were those reported by Burman in which he reports a series of cases treated with radium. It is essential for the proper treatment of these cases that a large quantity of radium or radium emanation be available.

A somewhat abbreviated report of my cases is as follows:

FIG. 1.—C. H. S., Case No. 1579, Plate 1, showing large mediastinal tumor before treatment

CASE 1579. (C. H. S. Age 45, White, Letter Carrier.) Patient first seen June 2d, 1920.

Complaint: Dyspnea, feeling of fullness in head on exertion, cough, backache and general weakness. Family history negative. Personal history and habits negative. Previous illness negative. December, 1919, patient noticed himself unable to carry load on account of fullness in head. Soon developed shortness of breath and cough, pain in middorsal region and swelling of neck and face. For the past two or three months appetite had been impaired, bowels constipated. Patient sleeps fairly well on right side, but unable to rest on left side or back. Unable to work or even take moderate exercise, though ambulatory. Has lost considerable weight.

Laboratory Examination: Wasserman negative, urine negative, R. B. C. 4,340.000, W. B. C. 6,000; Hem. 85 per cent., Polynuclears 77, small lymphocytes 15, large lymphocytes 3, transitional 5.

Physical Examination: Patient fairly well nourished. Hoarseness with persistent hacking cough, marked distention of veins of the neck, extending down over the chest and abdomen. Face swollen and edematous. Dyspnea on slightest exertion. Special examination of eyes, nose, throat, etc., negative. There was a slight bulging over the sternum. No evidence

of involvement of superficial lymphatics, no abdominal tumors nor evidence of involvement elsewhere. There was a well-defined area of dullness over the anterior superior portion of the mediastinum, extending downward continuous with the heart, which was pushed

Fig. 2.—C. H. S., Case 1579, Plate 2, showing partial absorption of mediastinal tumor four weeks after beginning treatment.

downward and to the left. Radiograph of chest demonstrated a large mediastinal tumor (See Fig. 1).

Treatment was begun June 2, on which date the patient received 19,400 millicurie hours of radium emanation, screened with 2 mm. of lead and 5 cm. of felt.

Fig. 3—C. H. S., Case 1579, Plate 4, showing complete absorption of mediastinal tumor

Approximately the same dosage was repeated at intervals of from one to two weeks during the following four months. There has been a gradual and consistent improvement of the symptoms and reduction in the size of the tumor (See Fig. 2).

Roentgenological and fluoroscopical examinations now show an entire absence of a tumor and reveals nothing abnormal in the chest (See Fig. 3). There has remained some venous congestion in the neck and some fullness of head upon extreme exertion. The patient has resumed work, however, and is feeling practically

Fig. 4.—G. A. S., Case 1371, Plate 1, showing large mediastinal sarcoma perforating the chest wall.

well. We shall continue this patient under observation with treatment at various intervals, and, while it is impossible to render a definite prognosis, we are quite optimistic regarding a permanent cure.

Case 1371. (G. A. S. Age 24, White.)

Complaint: Shortness of breath, cough and pain in the chest. Family history negative. Personal history and habits negative. Present illness: Patient enlisted in the Army Medical Corps in June, 1918. First noticed some swelling in chest in May, 1919. Examined by an army surgeon, who reported condition of no importance. Paid no more attention to it until November, 1919, when the patient first noticed some shortness of breath though the swelling had gradually increased. Several radiographs of the chest were taken and the tumor was aspirated, but no definite diagnosis was made until February, 1920, when a section was removed and diagnosis of sarcoma established. The patient was advised that he had but a few months to live

Fig. 5.—G. A. S., Case 1371, Plate 2, showing partial absorption of mediastinal tumor six weeks after the first treatment.

and was offered a disability discharge. He came under my observation February 9, 1920.

Laboratory Examination: Wassermann negative, R. B. C., 5,000,000; Hem., 95 per cent.; W. B. C. 6,000; Polynuclears, 87; Lymphocytes, 9; transitional, 4. Urine negative. Sputum negative.

Physical Examination: Well developed robust young man. Fairly well nourished. Dyspnea on exertion, slight cought, pain in chest, at times blood streaked sputum, voice husky, neck somewhat enlarged due to enlarged veins. There was present on the chest wall

Fig. 6.—G. A. S., Case 1371, Plate 3, showing total absorption of mediastinal tumor.

a tumor about 5 cm. in diameter and 3 cm. high, over the center of the right chondrocostal attachment of the third rib. Through the center of the tumor was a recent scar. Special examination of the mouth, ears, nose, and throat, negative. No involvement of superficial lymphatics, no palpable abdominal tumors nor evidence of involvement elsewhere.

Roentgenological examination confirming the physical findings, demonstrated a large mediastinal tumor, which penetrated the chest wall (See Fig. 4).

Treatment was begun February 11, at which time two platinum needles, each containing approximately 200 millicuries of radium emanation, were buried through the scar into the tumor mass. February 12 the same dosage was repeated, buried at different angles. February 15 to 27 the patient received several applications of approximately 20,000 millicurie hours each through various skin areas over the tumor. Applicator raised 5 cm. above the skin and radium screened with 2 mm. of lead and $^1/_2$ mm. of platinum. By the latter part of February there was a marked reduction in the size of the tumor and relief of symptoms.

During March, April, May, June, and July the patient received at various intervals of approximately two weeks dosage varying from 12 000 to 20,000 millicurie hours.

There was a continuous improvement in the symptoms and repeated physical and fluoroscopical examinations revealed a gradual absorption of the tumor, which by July 1 had entirely disappeared (See Figs. 5 and 6). The patient was able to resume work as a draftsman in August, has since married and is apparently in normal health.

The patient's present condition is a marked contrast to that at the time of coming under treatment, far more happy than the fatal prognosis rendered at the time of his army discharge.

Case 1643. (S. M. F. Age 65, White, Manufacturer).

Complaint: Pain in chest and neck, radiating down left arm, dyspnea, slight cough and general weakness. Family history negative. Personal history and habits negative.

Present illness: Seven years ago a small tumor was removed from outer condyle of right femur. Recurred at once and later right leg was amputated at thigh. Was apparently well until two years ago when patient noticed pain in left arm. Had various treatment without improvement. Patient came under my observation August 3, 1920.

Examination: Man past middle age, poorly nourished. Veins of neck markedly dilated. Marked irregular enlargement of thyroid gland, more prominent on right side. Though no distinct tumor could be outlined, there was a marked enlargement on both sides of posterior triangles just under the trapezius muscle, more prominent on left side.

Physical, roentgenological, and fluoroscopical examinations revealed an irregularly shaped tumor about 15 cm. in diameter, in the superior mediastinum extending under the clavicle (See Fig. 7). This is unquestionably a metastatic sarcoma involving the thyroid and mediastinal lymphatics.

Special examination, negative. Physical examination reveals nothing abnormal in the lungs. Heart slightly dilated, sounds regular and somewhat faint.

Treatment was begun August 5 and continued through September and October at intervals of from one to three weeks. From 10,000 to 20,000 millicurie hours were given at each application, the applicator being moved over various skin areas raised 5 cm. above the skin and screened with 2 mm. of lead and 0.5 mm. of platinum.

There resulted a prompt improvement of the symptoms, which have gradually subsided. Patient has gained in weight and strength. Pain, cough, and dyspnea have disappeared and the patient is enjoying practically normal health, enabling him to return to work on November 1. The mediastinal tumor has disappeared, also the enlargement in both posterior triangles of the neck. There is a marked decrease in the size of the thyroid and less dilatation of the veins of the neck.

The prognosis in this case is quite favorable and the improvement most gratifying. This case will also be kept under observation and will receive some additional treatment over the thyroid at intervals for some time.

Cases No. I and II, primary sarcoma of the mediastinum, in which involvement of the adjacent organs probably had not occurred, responded promptly to treatment and warrant a very favorable prognosis. Case III is a very interesting example of metastatic mediastinal involvement show-

Fig. 7.—S. M. F., Case 1643, Plate 1, mediastinal tumor extending into the triangles of the neck

ing the palliative and probable curative effect of radium therapy in these cases.

While it is too early to warrant any conclusions in the cases here reported, the great relief afforded by the appropriate use of large quantities of

radium is quite evident and there is reason to hope for a permanent improvement in some of these cases.

CHRONIC NON-TUBERCULOUS LUNG DISEASE.

BY HORACE GREELEY, M.D.,

BROOKLYN, N. Y.

IN an article* which appeared in the April number of the *Journal of Laboratory and Clinical Medicine* an account was given of investigations into the bacteriology of the sputa of some thirty cases of chronic non-tuberculous lung disease. The specimens were obtained from patients of two large institutions for pulmonary tuberculosis (Sea View Hospital and Otisville Sanatorium) and from the practices of various New York and Brooklyn physicians. While the chief interest of the work described was the bacteriological evidence adduced that the higher fungi and yeasts isolated could develop into and grow as typical bacilli, and even coccoid forms, sufficiently shown for the purposes of this article by the accompanying illustrations, there was enough of clinical interest and importance to justify recapitulation here, especially since new and additional data are at hand in connection with the vaccine treatment of such cases.

Bacteriology.—As smear examinations of the sputum, in most of the cases, showed yeasts and forms suggestive of the higher fungi (moulds), a medium [lactic-acid-agar] was devised which would act selectively in the cultivation of such forms, and upon this plants were made from the various specimens, and cultures incubated at both body and summer (70°-80° F.) temperatures.

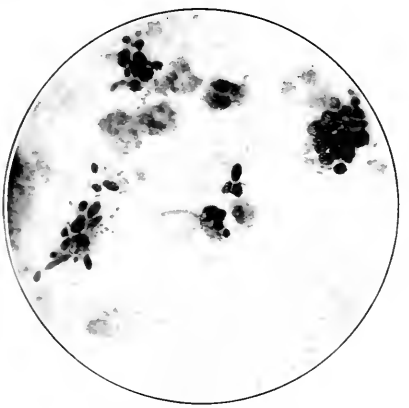

FIG. 1.—*Penicillium glaucum;* yeast bodies in sputum of Case XXIII. × 730.

In this way it was found that the sputa of fourteen of the cases contained the *Penicillium glaucum;* of two the *Mucor corymbifer;* of one, *Aspergillus fumigatus;* while that of thirteen cases gave (on culture) only yeast forms which, since we were unable to develop them into complete higher fungi, were classed together as "Aborted Fungi."

Quotations were given from various European

FIG. 2.—*Penicillium glaucum;* sporulating growth on slide. × 260.

authorities to show that the organisms in question were recognized as causes of disease, both in men and animals.

Clinical Character of Cases.—Cases With Physical Signs of Lung Infiltration: In six cases, varying from one to sixteen years in duration, physical examination of the chest was recorded as indicating infiltration of one apex; in two cases, of two and three years' duration, of both apices; in eight, of six months to eight years' duration, of one upper lobe; and in four, of from six months to nine years'

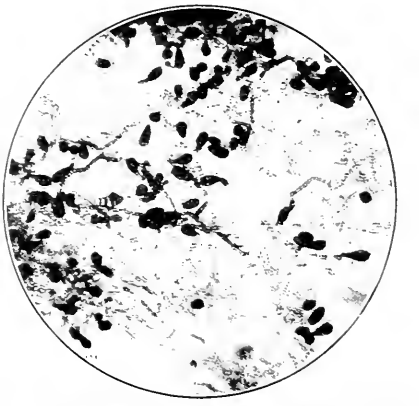

FIG. 3.—*Penicillium glaucum;* unusual mode of sporulating, conidia being contained in pods (sporangia); grown on slide. × 260.

duration, of both upper lobes. One case, of two years' duration, had a cavity at the right apex and some infiltration of both lower lobes. Most of these cases had shown, at one time or another, clinical manifestations similar to those of lung tuberculosis,

*"The Bacteriology of Chronic Non-Tuberculous Lung Disease," by Horace Greeley, M.D., and Mae Brereton.

but, almost without exception, of a milder type than would be associated with a tuberculous infection of similar extent. Expectoration was usually not so large in amount, nor so purulent and, very frequently, was of a type which may be described as

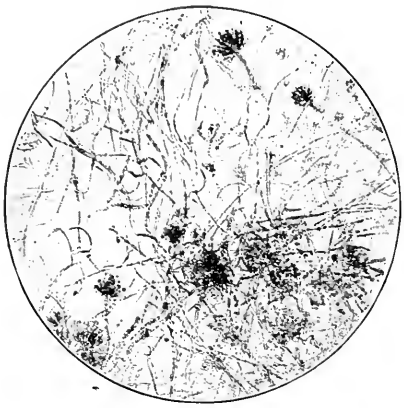

FIG. 4.—*Aspergillus fumigatus;* sporulating growth on slide. × 260.

watery with whitish flakes. As a rule, loss of weight was but slight, and fever and debility were rarely marked.

Chronic Bronchitis: Six of the cases had been classed by their medical attendants as chronic bronchitis (they had lasted one to twelve years) and were of patients of ages varying from 9 to 61. One of these, a boy of 9 years, showed evidence of slight fibrosis of the upper lobes and some swelling of the glands of the neck. He coughed considerably, showed but slight febrile reaction, little loss of weight, but considerable debility, which progressed

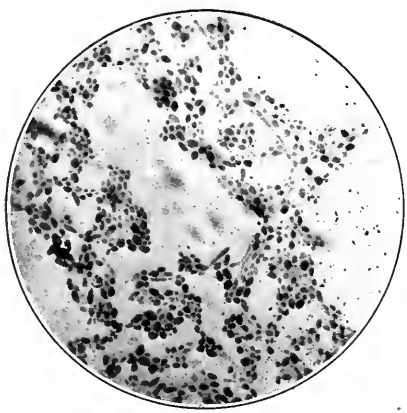

FIG. 5.—Aborted fungi, yeast form and a few branchings from Case XII (*a*). × 520.

sufficiently to cause his death after nine months.

Acute Bronchitis: Two cases of severe acute bronchitis, limited to three weeks, were included, since their sputa had been examined for the causative agents with interesting results.

Bronchial Asthma: Three cases, of from five to sixteen years' duration, of typical bronchial asthma are included in the series (only two of these were mentioned in the article alluded to).

Diagnosis.—The diagnosis of chronic non-tuber-

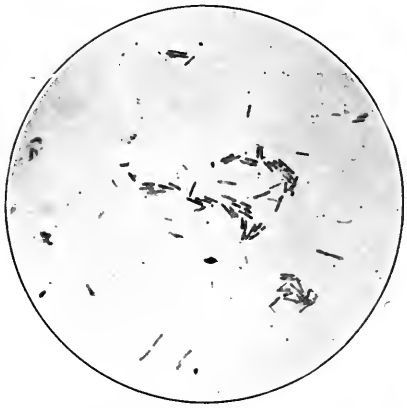

FIG. 6.—Branchings (now bacillary in form) only; this culture, Case XII (*b*), was the result of replanting branchings from culture of Case XII (*a*) by taking only the fringed edges of the colonies. × 520.

culous lung disease was made, in the cases in question, as the result of numerous (as many as forty-two in one case) recorded sputum examinations for tubercle bacilli, which had resulted negatively; and by the finding of organisms (fungi) known to be capable of causing such lesions.

In detecting such organisms in the sputum, while their presence could often be noted on smear examination, their identification always, and sometimes even their demonstration, required special cultural procedures.

Treatment.—In making a diagnosis of non-tuberculous fungoid lung disease treatment is greatly facilitated, since one is then free to push medication, as by the iodides (reported as having often been used effectively in these conditions), a procedure which would be considered dangerous with tuberculous lung disease. Besides this, autogenous vaccines may be made and prove beneficial. Some idea of the effect of such vaccines in these cases may be gained from the following case reports:

Penicillium Glaucum Vaccine.—To one case (Sea View Hospital) Dr. E. S. McSweeney gave eight doses, running from 0.055 to 0.4 c.c. of a suspension of 3,000,000,000 organisms, at a time, over a period of two months. As the injections gave rise to marked local and general reactions (including increased cough, expectoration, and fever) they were stopped. The specific reactions elicited may be regarded as confirming the bacteriological diagnosis.

An apparently successful use of an autogenous vaccine made of this organism was reported by the attending physician (Dr. J. M. Raub, Brooklyn). By it, apparently, the patient, a houseworker, 61 years of age, who had suffered from chronic bronchitis for twelve years, was entirely rid of her symptoms.

Mucor Corymbifer Vaccine.—One of the cases from whose sputum this organism was isolated was a man of 60 years, weighing 186 pounds. His physician (Dr.

O. M. Leiser, New York) had treated him for bronchial asthma for sixteen years, but he had developed a very severe cough at the time I examined his sputum. An autogenous vaccine was made, but I was informed no reaction nor improvement followed its use.

Aborted Fungi Vaccine.—Two cases are quoted: S. R., a man of 54 (patient of Dr. Charles M. Fisher, Brooklyn) had suffered from severe chronic bronchitis for eight years. On several occasions, Dr. Fisher says the patient developed a low grade bronchopneumonia, and altogether was greatly debilitated by the illness—*blood pressure*, 95. The patient was given 12 c.c. of an autogenous vaccine containing 2,000 million blastomycetes (yeasts) in 1 c.c. and 12 c.c. of a similar vaccine, which, besides the blastomycetes, contained three other organisms grown from his sputum, over a period of several months. Although reactions were not noticeable, Dr. Fisher says the patient made great improvement, cough and expectoration being reduced to a minimum, and blood pressure rising to 120, with commensurate return of strength and well being.

R. H., a woman of 31 (patient of Dr. Frederick M. Albers, Brooklyn), had suffered from severe attacks (confining her to bed for weeks) of bronchial asthma during some eight years. An autogenous vaccine (containing blastomycetes, 90 per cent.; micrococci, 10 per cent.) was made, and 12 c.c. given over a period of some weeks, with complete amelioration of the condition. There was, at least, one marked reaction after injection. Patient experienced a slight recurrence, recently, which lasted two days.

While I have records of other cases of chronic bronchitis and bronchial asthma in which vaccines were made, and considerable improvement, or even cure effected, as no attempt was made to identify the organisms found, the cases do not fit here.

The vaccine treatment of chronic non-tuberculous lung disease, including chronic bronchitis and bronchial asthma, should be effective, and confidence is felt that, if physicians will bear in mind the cardinal principles of vaccine therapy, success will attend well regulated treatment. A vaccine is only a stimulant to the natural curative powers and therefore results depend, not upon the injected material, but upon that which may be produced in response to its action. Therefore, we must look to the reactions which follow an injection for indication that such production is under way, and the size of doses and intervals between them must be regulated according to the effects of previous injections.

In such conditions as we have under consideration it is suggested to start with a dose of 500 million organisms, and then, at the end of three days, consider the size and time of the next dose. If a distinct local (at the point of injection) reaction, with definite swelling and redness follows the injection, this evidence of the desired stimulation renders it unnecessary to increase the dose at all, or certainly to not over 10 per cent. Reinjections had best never be made until 24 hours after the subsidence of all reaction—this usually brings them around every three days; and the same interval had best be allowed when there is no reaction. Noticeable focal reactions (heaviness over chest, increased or diminished cough and expectoration) and even constitutional manifestations, such as elevation of temperature, may occur, and indicate a maximum stimulation. Such reactions had best be followed by reduction in doses.

In case no reaction is elicited by a dose, the next had best be increased 25 per cent., and so on. In case a patient persistently fails to react—say after the initial dose of 500 million has been increased tenfold—the administration of potassium or sodium iodide, to the extent of 15 to 30 grains a day, may be tried in conjunction with the vaccine, since it seems that iodine arouses the reactive mechanism.

It is claimed that good results may follow vaccine treatment without noticeable reaction, but those cases showing the latter certainly make the greatest improvement.

140 CLINTON STREET.

ROENTGENOGRAPHIC TECHNIC WITH BUCKY DIAPHRAGM.

BY WILLIAM H. DIEFFENBACH, M.D.,
A. J. BARKER SAVAGE, M.D.,
AND
LOUIS FOX, M.D.
NEW YORK.

IN the MEDICAL RECORD of March 19, 1921, we published a preliminary report of the technic developed at Broad Street Hospital with the Bucky diaphragm, and further laboratory experimentation has added to the data which we desire to present with a few

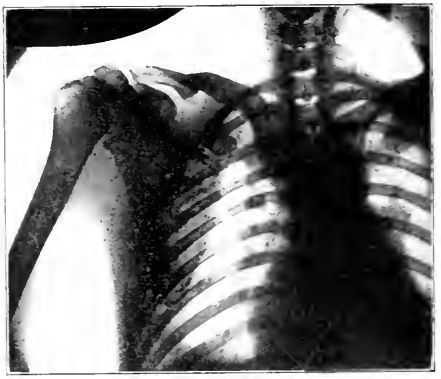

FIG. 1.—Shoulder joint.

electrotypes of pelvic and other films to demonstrate the value of this procedure.

The general points of technic are as follows:

1. Distance from tube to upper surface of Bucky diaphragm, 28 to 34 inches; the former in slender and the latter in stout persons.
2. Milliamperage—7 to 10 M. A.
3. Spark gap—3½ to 4 inches.
4. Tube—Coolidge-radiator type.
5. Bucky diaphragm.
6. Double intensifying screens and duplitized films.

The *variable* factor, with the above practically standardized methods, is the question of time of *exposure* of the films.

After testing a large number of films the following is our table of exposure as used at Broad Street Hospital:

Skull	8 to 10 seconds
Sinuses	10 to 15 seconds
Vertebræ cervical	6 to 8 seconds
Vertebræ dorsal and lumbar	15 to 18 seconds
Lateral spine	20 to 25 seconds

Pelvis and hip	18 to 20 seconds
Shoulder	4 to 7 seconds
Thorax	3 to 5 seconds
Elbow	3 to 5 seconds
Wrist and hand	2 to 4 seconds
Femur	4 to 7 seconds
Kneejoint	4 to 7 seconds
Tibia and fibula	3 to 5 seconds
Ankle and foot	3 to 4 seconds
Gall-bladder studies	6 to 10 seconds
Urinary tract	10 to 15 seconds

FIG. 2.—Pelvic area.

Calculi appear to be slightly enlarged with hazy border, but by firm immobilization and slightly lowering the distance a sharp detail is secured.

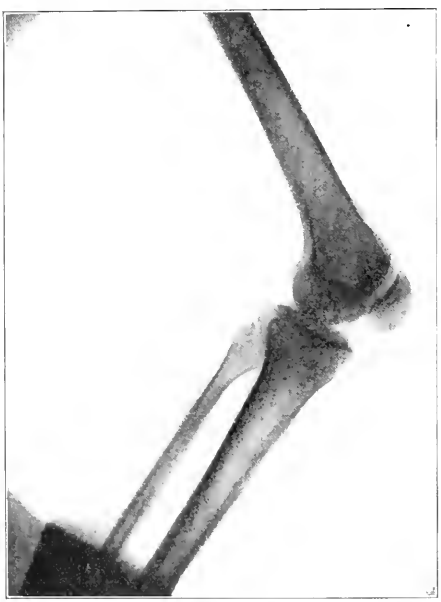

FIG. 3.—Knee joint.

We do not use the Bucky method in gastrointestinal exposures, as the old methods are quite satisfactory in every respect. In fact, the longer exposures of the Bucky diaphragm would be a drawback for detail.

The principal advantage of this technic appears

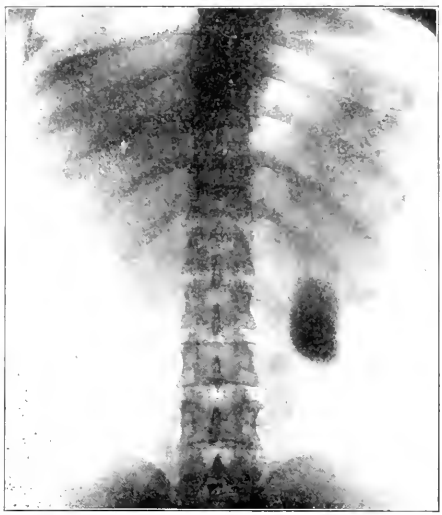

FIG. 4.—Calculus in the kidney.

to be its application in all osseous lesions and studies and its particular and unique value is in heavy tissue work such as the pelvic and hip exposures. Here large areas can be successfully taken on one film 14 x 17 with uniform detail. The whole pelvis, with both hips, can be demonstrated on one plate with even shadows.

In the small bones and small joints the use of the Bucky diaphragm method seems superfluous, as the old methods as a rule give excellent results, but in the large joints and heavy tissues the new method as outlined presents a decided step forward in Roentgen technic.

In the technic of the Bucky diaphragm beginners are advised to test the mechanism before exposure, and when ready for the film exposure start the grid for a few seconds before exposure and keep same going a second or two after exposure.

The senior writer desires to thank his colleagues, Dr. Savage and Dr. Fox, for the many hours spent in the development of the exact technic as outlined in this brief résumé.

50 CENTRAL PARK WEST.

Bovine Aphthous Fever Not Transmissible to Man.—Leclainche reports the discovery by Lebailly that the bovine aphthous fever is not transmissible to mankind, while human aphthous fever is likewise not transmissible to bovines. Although it has been taught since 1834 that human beings can contract foot and mouth disease from the milk of affected cows, Lebailly has succeeded in throwing serious doubt on this statement. —*Le Bulletin Medical.*

THE DELETERIOUS EFFECTS OF THE BROMIDE TREATMENT IN THE DISEASES OF THE NERVOUS SYSTEM.*

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

IN this paper I wish to discuss the dramatic and disastrous symptoms which result from the use of the bromide salts in the treatment of nervous diseases. By these I do not mean the rash, the cachexia, the feebleness, and the depression, but the confusion, the restlessness, the violence, and the syndrome of symptoms resembling mania and paresis.

Bromide is a remedy so constantly used and so constantly abused that it will not be out of place first to call to your attention just what are its effects upon the nervous system.

"Bromide," according to Hare, "affects the brain, cord, and peripheral nervous system. It slows the development of thought, decreases the excitability and power of the motor cells of the brain, and is a distinct depressant to the mental and intellectual portions of the cerebral cortex. Upon the cord it exerts a marked sedative effect so that reflex action is decreased and the motor pathways are depressed. Motion is maintained after sensation to pain and reflex action is lost. In this way damage is done without either patient or physician being alive to the fact. It also depresses the peripheral parts of the sensory nerves."

The results upon the peripheral nervous system are slight and infrequent as compared with those upon the cord and these in turn are neither so severe nor so frequent as are those upon the higher centers. The areas of the cortex are very greatly depressed, as Bastedo has proven by his experiments. He found that in the case of a bromidized dog it was impossible to produce convulsions by the artificial stimulation of those cortical areas.

There are several conditions in the nervous system in which the bromide salts are used. It would take much more time than I have at my disposal this afternoon to consider each one. I propose, therefore, to say a few words about some of the most frequent. I shall speak of the use of bromide in the following eight conditions: (1) Epilepsy, (2) toxic cases, (3) mental conditions, (4) traumatic and arterial conditions, (5) cases requiring long continued use of the drug, (6) alcoholic cases, (7) cases with an idiosyncrasy, (8) cardiac cases.

1. *Epilepsy.* It has long been recognized that there are certain types of epilepsy in which the use of bromide aggravates both the irritability and restlessness preceding the seizure as well as the depression following. Observers have reported cases of idiopathic epilepsy of long standing in which the administration of even moderate doses of bromide controlled the convulsions but substituted for them confusion, furor, violence, kleptomania, delusions, and homicidal tendencies. Weir Mitchell described such a case in 1887. The patient was an epileptic of many years' duration. Inasmuch as moderate doses had reduced the attacks, the attending physician reasoned that larger ones would stop them. As a result the bromides were increased until the patient was taking 150 grains a day. The patient became thoroughly intoxicated, the eyes partly closed, the sphincters relaxed, and the jaw dropped, emitting a constant drool of saliva. The major symptoms ceased but the minor ones increased. The mind became profoundly affected so that the patient was hard to arouse, indifferent, and imbecilic. Allen Starr reported another such case in 1896. His patient, under the administration of moderate doses of bromide, developed symptoms of violence and mania. In this instance a withdrawal of the drug produced a complete cessation of the maniacal phenomena with a return of the epileptic seizures.

I have seen the same condition. A young man, who had suffered from epileptic convulsions for many years, required 60 grains a day of the bromide salts to arrest the attacks. If he continued this dosage over a long period of time he would become confused, irritable, unreasonable, and violent. On one occasion he attacked a fellow workman. So soon as the bromides were reduced his mental symptoms abated.

It is in keeping with these facts that Shanahan, the superintendent of the Craig Colony, makes this statement in regard to the use of bromide in the treatment of epilepsy, that "bromide, when properly given, with due attention to combating the evil effects, brings about material improvement in *carefully selected* cases of epilepsy."

It seems to be the epileptic cases of long standing which show an especial antagonism to the excessive use of the bromides. I believe that the irritability of temper displayed by these long-standing epileptics is as much, if not wholly, due to the constant and excessive use of bromides as it is to the disease. In the administration of bromide in epilepsy, therefore, one should exercise caution, judgment and moderation. A patient should never be saturated, and the presence of unusual irritability, confusion, or violence should be the signal for a decrease in the dosage. At the present time when luminal has given such brilliant results in controlling the convulsions of epilepsy, it would seem that the administration of bromide in this disease would soon become obsolete.

2. *Toxic Cases.*—The toxic and exhaustion cases react unfavorably to the administration of bromide. They are suffering from lowered resistance and impaired nutrition, therefore, what to an ordinary individual might be an average dose of bromide, becomes to one of these patients a dangerous dose. A careful investigation and an exhaustive history of these patients will prove that in nearly every instance the mental symptoms of confusion, delirium, and mania, either made their appearance shortly after the administration of bromide, or were greatly aggravated by it. I remember one such patient where fatigue and insomnia were followed by sedatives, hypnotics, and finally steady and progressive doses of bromide. Shortly after the patient was said to be developing a psychosis with symptoms of confusion, irritability, restlessness, mania, and suicidal tendencies. In this connection I might mention the post-operative cases. These have slightly lowered resistance, amorexia, weakness and insomnia. To help them bromides are given, at first in small, later in large doses. At the

*Read at the Annual Meeting of the Medical Society of the State of New York at Brooklyn, May 4, 1921.

end of a few days maniacal symptoms appear. I can recall two such post-operative cases, seen in two of the best known hospitals in New York. These patients had been unable to sleep. After the first night, when morphine had been given, resort was had to bromide. The dose had been gradually increased until maniacal symptoms appeared. It is not uncommon for physicians to administer forty grains of bromide four or five times in twenty-four hours and to continue this for several days. Such dosage invariably ends in symptoms of bromidism. A short time ago I saw a post-operative case that had been given 1400 grains of bromide in one week. All of these patients developed the same type of symptoms—confusion, delirium, delusions, great restlessness, and violence. The onset of the maniacal symptoms appears to be sudden and as is always reported "the symptoms became worse in spite of 60 grains of bromide given every night."

3. *Mental Cases.*—Mental cases are susceptible to bromide intoxication. This is due to the fact that these patients are suffering from a long drawn out condition, that their nervous system is vulnerable, that their resistance is lowered, and that their cerebral circulation is poor. The anxiety, restlessness, and insomnia so frequent in mental conditions has required the constant administration of sedatives and, therefore, these patients are mildly toxic. Bromide is frequently given in these cases, at first in small and finally in large doses. As the symptoms fail to abate the dosage of the bromide is increased and as the symptoms augment is again increased. Finally a condition of bromidism is induced on top of the existing mental condition.

I remember not very long ago seeing a patient who was very confused, delusional, and restless. She had a foul breath and coated tongue, there was a tremor of the hands, the gait was ataxic, and the Romberg symptom was present. The pupils were sluggish and dilated. She was garrulous and incoherent. Naturally, the tentative diagnosis was paresis. She was sent to a hospital for diagnosis. The blood and spinal fluid were reported negative. I decided to keep her under observation. Her confusion began to subside. She became less tremulous and less talkative. There was evident improvement. In a few days more she began to walk and the Romberg symptom disappeared. In two weeks this patient changed completely. All her paretic symptoms disappeared. A careful investigation, together with admission on the patient's part, revealed the fact that she had been depressed for months and unable to sleep. She had obtained a prescription for bromide, which she had taken constantly whenever she felt nervous, and gradually had become intoxicated.

4. *Traumatic and Arterial Conditions.* — I have had no personal experience with traumatic cases and bromide dosage. Weir Mitchell, however, cited a case of a man injured in a railway accident, who took bromide to relieve insomnia. His physician advised him to stop and later on, thinking that he had obeyed him, prescribed small doses of bromide. Soon the patient developed irritability of temper, confusion, and violence. It was not for some time that it was discovered that he was getting the double dose of bromide. A complete stoppage of all drugs caused an abatement of his symptoms and a return to a normal state.

It is to be expected that patients suffering from arterial changes would be peculiarly susceptible to bromide as they are to all kindred drugs.

5. *Bromidism from long continued use of bromide, after the discontinuance of the drug.*—There are a certain number of instances in which the diagnosis of bromidism is made and, even after the drug is stopped, the mental symptoms persist. These cases are confusing. The reasons for their occurrence are twofold: (1) the slow elimination of bromide, and (2) the fact that bromide is stored in the tissues in depots so that long after the drug has been stopped, the patient is still being intoxicated as he is drawing upon his bromide reserve. So slow is the elimination of bromide that it has been discovered in the urine a month after the administration of the drug has been stopped. Simankowsky found traces of it in the urine of a dog four months after stopping bromide.

6. *Alcoholic Cases.*—Alcoholics are susceptible to bromide intoxication. They of course are already toxic, have poor circulation, and suffer from lowered resistance. The drug should be given them with great caution. It is, however, constantly administered, both in large and frequent doses. Two years ago I saw a patient in a maniacal condition, noisy, confused, and violent. She had been drinking slightly but over a long period of time. Finally, when depression and insomnia developed, she consulted a physician, who prescribed bromide. She had the bottle constantly refilled and whenever tired or depressed took a teaspoonful. Gradually there developed confusion, violence, mania, and then delusions. Her condition was not recognized. It was impossible to know that she had been taking the bromide, so to quiet her, more bromide was given. This patient became more noisy and violent than any of the other bromide cases that I have seen. She became suicidal and at one time swallowed a large diamond ring. There were no untoward symptoms and the ring was passed and recovered two days later. Withdrawal of all medication from this patient resulted in a complete recovery.

7. *Idiosyncrasy.*—There are, of course, certain persons who display an idiosyncrasy to bromide. These develop the same train of symptoms. Just why one man can take forty grains daily and another cannot is difficult to explain.

8. *Cardiac Cases.*—Da Costa first called attention to the fact that while the bromides do not generally disturb the circulation they may do so when certain functional failure of heart force exists. In a few of these cases of chronic heart disease not only do small doses of bromide depress and enfeeble the heart, but if long continued cause the paretic symptoms so common in this condition.

The symptoms of bromidism are therefore twofold: (1) Physical and (2) Mental.

1. The *physical symptoms* are the rash, the coated tongue, and fetid breath, constipation, cachexia, feebleness, an excessive flow of saliva, and, if the condition is aggravated, an ataxic gait, a loss of patellar reflexes, tremor, and an ataxic speech.

2. The *mental symptoms* are restlessness, insomnia, depression, later excitability, confusion, delusions, and hallucinations.

The conclusions to be reached from this little study are

1. That bromides are very far from harmless.
2. That their prolonged administration will give rise to both physical and mental symptoms, the latter a condition akin to paresis.
3. That they tend to aggravate the irritability and mental deterioration in long standing cases of epilepsy.
4. That toxic cases develop more rapidly upon the administration of bromide.
5. That circulatory, traumatic, and arterial cases are peculiarly susceptible to their administration.
6. That bromide may mask the symptoms of mental disease just as thoroughly as does opium in surgical conditions.
7. That mental and alcoholic cases are peculiarly susceptible to bromidism.

41 EAST SIXTY-THIRD STREET.

SOME UNUSUAL OBSTETRICAL AND GYNECOLOGICAL CASES.

BY LUCIUS FELIX HERZ, PH.B., M.D.

NEW YORK.

ASSISTANT GYNECOLOGIST, NEW YORK POST-GRADUATE HOSPITAL.

In 1916 I was called to see a young woman of twenty who had fallen in a faint. I found her seven months pregnant, and found that she was a primipara with an extremely rigid cervix. A specimen of urine boiled solid. The patient had had vomiting and dizzy spells for several weeks. I sent her into the wards of a maternity hospital, where she passed out of my control, although I kept in touch with the case. Accouchement forcé was performed. The cervix was dilated with difficulty, and packed. Delivery of a dead child occurred forty-eight hours later.

I consider that the operation of choice in this case would have been a cesarean section, and this for three reasons: Firstly, the chances of a living child are far greater. Secondly, the toxemia would be stopped more rapidly. Even the difference of a day might mean the difference between recovery and not. Thirdly, maternal morbidity is far less in a cesarean section. In an accouchement forcé, deep tears of the cervix are common; they may run into the lower uterine segment, or laterally into the broad ligament, or they may even cause a true rupture of the uterus with extremely probable maternal death. As for postoperative pneumonia, that chance must be risked. As a matter of fact this particular patient subsequently developed a postoperative pneumonia, following the slight amount of anesthetic she received when her cervix was dilated. She would undoubtedly have developed it also with a cesarean operation, but the majority of patients would not develop pneumonia, as the toxemia would be recognized earlier, and either benefited by palliative means or operation performed before the toxemia became so great. Toxemias are now greatly benefited by endocrines, but that is a new story, and we were not using them at the time this case occurred.

In September, 1920, I was called to see a primipara who presented a frank breech. Attempts to deliver as a frank breech were without avail, owing to the resistance of the soft parts, and the only partial engagement of the breech. This was then pushed back, Pinard's maneuver was performed, and a breech extraction followed, with the regrettable mishap of a fractured femur, but a live baby. As the fetal mortality in breech cases is 10 per cent., an occasional fetal morbidity must be expected. The fracture was treated in a plaster cast, in the frog position, and united without deformity.

In January, 1921, I had two cases of compound presentations, both showing an arm well extended with a head partly engaged. The first patient was a primipara. Attempts to replace the hand and arm were without avail, so I had an assistant anesthetize the patient, performed a version, brought down the feet, and delivered her of an eight-pound child without complication. The second patient was a para IV, and was giving birth to triplets. The first child was a simple vertex, the second a shoulder and vertex, but as it was an extremely small child, and the second and third sets of membranes had ruptured within a minute of each other, I delivered the child with the arm extended, and gave the mother five minims of pituitrin, as she had no labor pains with the first child. The child was delivered readily without complication, as also was the third child. As none of the triplets exceeded five pounds in weight, it was perfectly safe to deliver a compound presentation as such, in this case.

In March, 1921, I was called in to see a para III, who was four months pregnant and had had uterine hemorrhages for the past two months. She had had two previous deliveries by cesarean section, on account of a generally contracted pelvis. At the last operation, performed by a well known gynecologist, the tubes were ligated, and the patient was assured that she could not again become pregnant. She had had one attack of pleurisy, and had also had an operation for osteomyelitis of the tibia. I prescribed some codeine for her, and left orders to be kept informed as to her condition. A day after she was first seen, she aborted, and was attended by her mother who is a midwife. I was called in after all was over, and found the abortion complete. I am very dubious about the sterility of the midwife's technique, and disclaim all responsibility for the complications that followed. Five days after the abortion, the patient had a violent chill, followed by a temperature of 106°. The pulse was 120, and subsequently 145. Examination of the lungs were negative. I regarded the case as septic, and sent the woman into one of our general hospitals. She developed a bilateral lobar pneumonia a few days later, and this was followed by an empyema. A thoracotomy was performed. She continued to be septic, and a blood transfusion was performed. Shortly afterwards, she died.

The patient's husband blames the surgeon who had attempted unsuccessfully to sterilize her, for her condition, as he would have used precautions against conception otherwise. While this operation for sterilization was unquestionably improperly done, the true blame should be upon the midwife for improper technique. Undoubtedly the gynecologist who operated upon her ligated and cut the tubes close to the cornua of the uterus and the tiny stump of one of the tubes was still able to functionate. The proper way to perform this operation, of course, is to take out V-shaped portions of the uterine cornua with the tubes, ligate the tubes, and repair the uterine defect with mattress followed by simple sutures.

In March, 1921, I was called to see a para II, who was seven months pregnant, and was having a moderate uterine hemorrhage, having had had a similar one two weeks before. The cervix was soft, and admitted two fingers. The head was not engaged, but a boggy substance was distinctly felt. I diagnosed the case as one of placenta previa, and advised her to go to a hospital. She followed my advice, and I no longer had control of the case, but kept in touch with her. A version accouchement forcé was performed with delivery of a dead child.

I was the fourth physician called to examine this patient, and according to her statement the first to recognize her condition. The rest considered it a threatened abortion. It is surprising

that cases of placenta previa should so often go unrecognized, when we know that this condition is the most frequent cause of hemorrhage before delivery in the second half of pregnancy. Again, as to the proper treatment for this condition, I consider caesarean section the operation of choice for the same reasons that I have enumerated in the case of toxemia first described, and for the additional reason that severe and often fatal hemorrhages may occur during an accouchement forcé. What may appear to many people as a radical procedure, is frequently more conservative when properly done, than so-called conservative treatment.

On May 24, 1921, I was called by a midwife, to see a case she was unable to deliver. The woman was a para II, who had been in labor for forty-eight hours. The child was in the right occiput posterior position, and showed marked evidence of malformation. The fontanelles were obscured by a large meningocele, the size of an adult head. The features and ears, however, could be readily made out. Delivery by forceps was impossible as they would slip off. Version was impossible. Craniotomy was decided upon, and owing to the poor home surroundings, the child was delivered in Nursery and Child's Hospital, where the meningocele was perforated, and the child then readily delivered. The child showed a congenital absence of the right arm, webbed fingers on the left hand, a large meningocele as noted, six nostrils, a marked hare lip, and club feet.

I am reporting these cases to demonstrate that obstetrics is not always a simple matter, but frequently involves more responsibility than major surgery.

A woman of thirty-eight consulted me for a psychopathic complication associated with beginning menopause. She had had three children, normal deliveries. Menstruation had always been regular, every twenty-eight days, moderate in amount, painless, and of five days' duration, except the last three periods, which lasted only two days. The last one was two weeks before the onset of her psychopathic symptoms. She had the usual hot flashes of the menopause, and besides these had irresistible impulses. She would arise at three A. M., when fully awake (she could sleep very little), and wander through the house, and even into the street, in her night dress. She had strong desires to fling herself out of the window. She had an insight into her condition, and stated to me that she felt herself "going crazy," and was willing to go into a psychopathic ward, if I thought it necessary. I prescribed tablets of ovarian extract, each grain v., and tablets of thyroid extract each gr. i, both to be taken three times daily, and after taking these for five days she had a brief mentrual period, with immediate relief from her psychopathic condition. A month later she came to my office, and said she felt well in every respect. I considered it best, however, to continue the ovarian extract at the same dosage, and to give a reduced dose of thyroid, gr. 1/6, three times daily for some time to come.

My work in Bandler's clinic has convinced me of the efficacy of endocrine therapy in this condition, and in many others, which I cannot describe here, but which Bandler has described in considerable detail in his recent writings.

441 West Forty-fourth Street.

Uremia Without Nitrogen Retention.—The occurrence of terminal uremia in subjects with sclerotic kidneys without evidence of nitrogen retention has been seen by Brouardel and Renard. This case violates Widal's laws of the relations between nitrogen retention and uremia and apparently defies explanation. Edema was also absent.—*La Presse Médicale.*

AN UNUSUAL CASE OF MALIGNANCY.*

By EVERETT M. ELLISON, A.M., M.D.,

WASHINGTON, D. C.

CLINICAL ASSOCIATE IN MEDICINE, THE GEORGE WASHINGTON MEDICAL SCHOOL.

THE following case presents several points of interest which would seem to make it worthy of record.

Mrs. O. P. H. was born in the District of Columbia of a Danish father and an Italian mother on December 19, 1860. Her father died at 70 from tuberculous laryngitis, her mother at 65 from cerebral carcinoma. One maternal aunt died at 68 from cancer of the liver. Her two brothers died, one at 2 and the other at 30, from pulmonary tuberculosis. Her husband, a native of Virginia and a civil engineer by occupation, died at 57 from organic heart disease in 1912.

In 1891, at 31, our patient gave birth to triplets, one of whom was still-born. The other two are living and in good health at the present time. This labor was most tedious, and her recovery was quite slow. Her second and final pregnancy was terminated in 1897, when her third daughter now living and in good health was born. Early in this puerperium, she developed double mammary inflammation with suppuration which lasted for several weeks. Her general convalescence was long-delayed.

In 1898, our patient discovered what her family physician called a wen, located between the nipple and the upper margin of the right breast, which he advised her to let alone and forget. This mass was and remained for a long while about the size of a hen's egg, was superficial and readily movable. It gave no subjective symptoms whatever until 1905, when it suddenly became somewhat larger and painful.

She then went to Dr. Emory W. Reisinger, who looked upon the tumor with suspicion but was inclined to consider it non-cancerous. After keeping it under observation for about three weeks, during which Dr. Reisinger was seriously impressed by the rapidity of its growth, he called Dr. Henry D. Fry into consultation, who did not hesitate to recommend early operation. She was soon admitted into Dr. Fry's Sanitarium, where he performed a simple amputation of the right breast. Her recovery from this operation was rapid and quite satisfactory.

Mrs. H. passed through her climacteric at between 40 and 47 without incident, except for this operation at 45.

On April 27, 1919, fourteen years after this amputation, during which period she had been in apparently splendid health, she called me in to examine her left breast, which had lately become rather hard and painful in and close about the nipple. While in her bath a very few days previously, she had by chance first observed this condition. My tentative diagnosis was acute mastitis, for which simple local treatment was prescribed.

After one week, no manifest change in the condition having taken place, I called Dr. J. Wesley Bovee into consultation. He concurred in my tentative diagnosis and recommended the "let alone" treatment for a few days. As the same signs and symptoms were present at the end of another week, our patient was admitted into Columbia Hospital, and there a radical amputation of the left breast was performed by Dr. Bovee on May 12.

The specimen was sent to the Army Medical School for examination. It is stated in their report of May 23, "There is no tissue anywhere in all the specimen that can be recognized either macro- or micro-scopically as breast tissue." Their diagnosis was: "Metastatic carcinoma in lymph glands, fat and muscle tissue." The patient was discharged from the hospital in fair condition on May 31, the incision being slow to heal in the upper arm.

On June 20, I wrote to Dr. Howard A. Kelly of Baltimore for his advice as to the administration of radium in this case for prophylaxis. He replied that this

*Read before the Medical Society of the District of Columbia, February 16, 1921.

would probably be of great value, provided metastasis had not already taken place within the thorax.

On July 8, Dr. Thomas A. Groover made *x*-ray pictures of her chest and reported that he had found "No evidence of abnormality of heart, great vessels, lungs, nor of the mediastinum."

Mrs. H. went to The Howard A. Kelly Hospital for four radium treatments as follows:

August 19—1,028 mgs. for 40 min. applied to neck and breast.

August 29—3,398 mgs. for 25 min. over five areas of breast.

October 16—3 692 mgs. over neck, axilla, and shoulder, 60 min. to each area.

November 13—3,159 mgs. for 80 min. over four breast areas.

In the meantime, her left chest and arm had gradually become quite hard, swollen, and painful. It was readily observed that her condition was constantly growing worse and that the radium had signally failed to prevent recurrence or extension. It now became necessary to administer morphine in gradually increasing doses, and our patient went the usual way of such cases, suffering the agonies of death many times over until the end came on June 15, 1920.

It is a moot question whether the tumor of the right breast in this case was malignant. The patient, in talking with me, claimed to have had absolute assurance from Dr. Fry that it was benign. However, the head nurse at his sanatorium, claiming to remember the case perfectly well, declared very positively a few days ago that this tumor was, in Dr. Fry's opinion, according to his definite statement made at time of operation, unquestionably cancerous.

The patient's daughters have the facts in mind well enough to state without question or qualification that the right breast mass of 1905 (so far as *they* could see) was in no way similar to the left breast mass of 1919. Dr. Fry's case records were destroyed at his death in June, 1919, hence it has not been possible to ascertain in any direct manner what his real diagnosis was.

To Summarize.—1. Whether heredity is important in the etiology of cancer or not, it seems that this family history is rather significant.

2. It is an interesting coincidence, if nothing more, that this patient suffered abscessed breasts prior to the known development of any malignancy. In nearly 2,000 cancers of the mammary glands, MacCarty has never seen the condition except associated with a definite *chronic* mastitis. In almost the same number of specimens of chronic mastitis he has found histologic pictures that present changes with the demarkation to and including the picture of early carcinoma.

3. In view of the age of the first tumor and its conservative removal, the length of time elapsing between the two amputations and the excellent health of the patient during the interim, and the fact that Dr. Fry did not warn any member of the patient's family to be on the lookout for subsequent trouble, there is certainly room for reasonable doubt as to whether the right breast tumor was malignant.

4. This case is also of interest, along with many others on record, as showing how futile, if not worse than worthless, both surgery and radium are, sometimes, in dealing with early malignancy. And our retrospection leads us to wonder whether *x*-ray treatments would have been of value.

Medicolegal Notes.

Admissibility of Dying Declarations in Homicide Cases.—In a homicide case, where the dying declaration of the deceased was introduced in evidence, the Oklahoma Criminal Court of Appeals states the law as to the admissibility of such declarations as follows: Whether or not a purported dying declaration was made by a deceased under the sense of impending death is, first, solely a question for the trial court, in so far as it determines the admissibility of the declaration. In order to be admissible in evidence, it must sufficiently appear by evidence adduced on the preliminary hearing, had in the absence of the jury, that such declaration was made at a time that the deceased was under a sense of impending death, and that the declaration is restricted to facts concerning the facts and circumstances attending the homicide being tried, and, such facts being established, such declaration should be admitted in evidence, notwithstanding that subsequent to making such declaration the deceased expressed the belief that he would get well. It is not necessary that the deceased declare he is going to die. It is held sufficient if the circumstances, including his physical condition, and that he was too weak to sign his name to the declaration and so affixed his mark thereto, and that he four days after making such declaration died from the infliction of the wound to which said declaration relates, show at the time of making such declaration he believed he was going to die, and this renders said purported dying declaration admissible in evidence.—Elliott v. State (Okla.), 194 Pac. 267. Where a written dying declaration, for the admission of which in evidence a proper predicate has been laid, contains recitals of transactions had and statements made which do not shed light upon the homicide, and are not *res gestæ* in the strict sense, such recitals of transactions and statements are not admissible in evidence.—Wratislaw v. State (Okla.), 194 Pac. 273.

Construction of Washington Drugless Healers' Statute.—The plaintiff in a proceeding against the Washington State Board of Drugless Examiners, who had applied to the board for a license to practise, was issued a license to practise suggestive therapeutics, and, claiming to have been improperly classified by the board, he sought to have issued to him a license to practise mental therapy. The Washington Drugless Healers' Statute of 1919, section 4, provides for the issuance of the following certificates to healers: Certificates to practise (1) mechanotherapy; (2) suggestive therapeutics; (3) food science; (4) physcultopathy, and (5) any other separate and coordinate system of drugless practice.

The Washington Supreme Court has now reversed a judgment of the lower court ordering the board to issue a new license to the plaintiff, for the following reasons: "Subdivision (2), above, refers to a school of practice which operates through the mind of the patient, and whether the cure is secured by mental operations resulting from suggestions from the practitioner or from reasoning between the practitioner and the patient is of no importance. It was not the purpose of the Legislature, in providing licenses for these various systems of drugless healing, that each practitioner might choose for himself a name to describe his practice and be licensed under that name. Four distinct classifications are made, and a fifth is provided for systems which are separate and coordinate to the four systems specifically described. It cannot be said that the system explained by the respondent is separate and coordinate. The fact that it is possible to license persons to practise suggestive therapeutics whose method of operation is distasteful to the respondent does not privilege him to choose some other designation under which he would like to be licensed. Nor does the fact that the board may have erred and granted licenses under names not set forth in the statute, although the persons practising under such names are, in fact, practising what should properly be designated therapeutics, give to the respondent the power to compel the board to commit another error in his case."—Wells v. State Board of Drugless Examiners (Wash.), 194 Pac. 388.

PARADOXICAL REACTION OF THE PUPIL.

By this term is meant dilatation of the pupil caused by directing upon it a ray of light. It is worth while for clinicians to study this sign and to search for it, although for the present no diagnostic value can be assigned to it. But it should at all events cause one to suspect a serious organic affection of the nervous system, possibly of syphilitic origin. This reaction has been differently interpreted by various observers and its reality has also occasionally been denied. Some attribute it to a synergy of movement with the pupil of the other eye which has remained free; others regard it as a phenomenon depending upon the orbicular reaction of the pupil—Piltz's phenomenon—and in four cases recently published by Secret, his observation has led him to acquiesce in this way of looking at the phenomenon. Still other observers look upon it as the result of movements associated with those of divergence, movements which are favored by a paresis or paralysis of the adductor muscles of the eye, this being more especially the opinion of Frenkel. This observer therefore denies the paradoxical character of the reaction, and in two of his cases Secret was forced to recognize the justice of this interpretion.

However, some clinicians mention dilatation of the pupil under the sole influence of light and confirm its paradoxical character; three out of the nine cases reported by Secret unquestionably enter into this latter category. From various sources it would seem that we are authorized to admit that a reaction of a paradoxical nature of the pupil to light certainly does exist, although it is a rare phenomenon. For example, in a case reported by Burchardt, the patient, a syphilitic, had an iridectomy done for a left-sided iritis. The dilatation, induced by lighting the temporal side of the left pupil, was due to the contraction of the muscle of the iris, which brought the two free ends of the lower part toward the fixed attachment above and in so doing produced an enlargement of the coloboma. Lépine reasoned from analogy. Since a rise in temperature may occur following the exhibition of quinine, sodium salicylate, or antipyrine, so a luminous stimulant acting on the pupil may produce dilatation instead of contraction. Bechterew admitted the possibility of voluntary dilatation of the pupil and he reported the case of a neurotic woman who for five years was able to dilate her right pupil at will, just as some persons can control the heart beats. Another hypothesis, emitted by Money, is that the dilatation is produced by the action of the heat coming from the luminous source on the terminal fibers of the trigeminus. Bechterew offered still another explanation based on pathological researches on the subject of normal reaction of the pupil. The lesion is to be found in the nucleus of the oculomotor nerve, in the motor center of the iris, and consists of a softening of the cerebral substance. Should a process of cure ensue, the peripheral portion again resumes its momentarily abolished functions. This reorganization of the cerebral substance is characterized by a remarkable fatigue and consequently, with moderate light—that of day, for example—a slight contraction of pupil results, but an intense light will provoke an arrest of the reflex of the pupil at its very onset, the extent of which will depend upon the amount of exhaustion of the center of the iris.

Silex assumes that a permanent contraction of the sphincter of the pupil exists, due to some cerebral irritation or a spasm of accommodation. The rays of light falling suddenly on the pupil in these circumstances paralyze the active nervous fibers and thus gives free play to the dilator muscle. The paradoxical reaction has been explained by some by a phenomenon similar to hippus. Under normal circumstances the oscillations of nervous activity, by reacting on the tonus of the dilator of the pupil, provoke rapid oscillations of the diameter of the pupil, known by the name of hippus. The pupil, even in the physiological state when kept for a certain time under the action of light, may gradually dilate instead of contracting, and it is to a phenomenon of this kind that the name of paradoxical reaction has been given.

CONCERNING GOUT.

OPINIONS as to the diagnosis and consequently the treatment of gout are not so definite as formerly. It used to be, and not long ago, almost an article of faith that gout was due, if not wholly, at least largely to an excess of uric acid in the system. Of course, this belief is still widely held. These views must, however, undergo a considerable amount of revision if we are to accept the statements put forth in a paper read before the Dover and Folkestone division of the British Medical Association on April 7 by Llewellyn T. Llewellyn. (*Medical Press and Circular*, May 25 and June 4, 1921.)

In the first instance it has been demonstrated by modern research that the diagnosis of gout cannot rest solely on the analysis of the urine, but must depend also on the quantitative analysis of the blood. A fairly accurate means of this form of blood analysis was rendered possible by the introduction in 1913 of the colorimetric system by

the American biochemists, Folin and Denis. These investigators were able by this technique to show that uric acid is a normal constituent of human blood, even when persons are fed on a purin-free diet. The uric acid content of the blood in individuals suffering from gout exceeds that of normal individuals by only a few milligrams. Therefore, as Llewellyn points out, we are asked to believe that this trifling amount possesses such profound potentialities as to determine the incidence of gout. As a matter of fact, the blood stream can hold in suspension far more uric acid than has ever yet been met with in gout. Moreover, further difficulty must be surmounted; to-wit, that in diseases other than gout a still greater percentage of uric acid may be found in the blood; yet gout is not developed. And still another discrepancy hard to explain satisfactorily has to be noted. An excess of uric acid is not peculiar to gout and is not always present in gout. From a study of these and other considerations, Llewellyn comes to the following conclusions: (1) Uric acid is a normal constituent of the blood. (2) Only by a few milligrams does the blood content in gout exceed the normal. (3) An excess of uric acid in the blood is not peculiar to gout, but is met with in other diseases, and in larger amounts. (4) No constant relationship has yet been established between the uric acid content of the blood and acute attacks of gout. (5) Attacks may occur, even when the uric acid content is subnormal. As for the physiological effect of drugs, phenylcinchoninic acid, which increases uric acid elimination and augments the output by the kidneys, does not necessarily inhibit the incidence of gouty paroxysms, while colchicum, according to Dixon and Malhen, has no action on metabolism or the excretion of urine, nor on the kidneys. In short, it exerts no influence whatever on uric acid excretion. But, although colchicum is the remedy par excellence for acute gout and will not be supplanted by any other remedy which quickly and markedly increases uric acid excretion, phenylcinchoninic acid does influence the consequences or sequels of gouty inflammation—that is to say, it obviates the formation of the sequential uratic deposits, or promotes their absorption and elimination when established. Judging, then, from the contrasting physiological action of these two remedies and from the results of urine and blood analyses, uric acid is not the cause, but, at the same time, has something to do with the causation and the sequelæ of gout.

It is Llewellyn's belief that infection is a prominent factor in the genesis of gout, and pyorrhea may be a predisposing cause of the disease, as may also be infected tonsils. Attention is drawn to the fact that gout suggests infection in more ways than one. The abrupt onset, the temperature curve, the character of the local phenomena, and the course of the disorder are emphatically indicative of the intrusion of an infective element. In conclusion, it is pointed out that there are many analogies between gout and the specific infective arthritides. For example, in virtue of its tendency, not only to arthritis, but to trouble of nerve and muscle sheaths, gout falls into line with the specific infections. Its predilection for bursal and fascial structures is but another evidence of affinity with this group of diseases. In view of these similitudes, one may well ask, are not the manifestations of gout, all of them, susceptible of a like explanation? For in reviewing the clinical and pathological data brought forward by him, Llewellyn thinks, it cannot be gainsaid, that they are more readily explicable by the theory of an infection than in any other way.

It is no new contention that gout is not caused by a system loaded with uric acid alone, but the assertion that its manifestations are due to a specific infection requires further proof before it can be generally accepted. So long has the belief been held that gouty arthritis is of purely metabolic origin that it will not be easily overturned. If it were not, at any rate mainly, a disease of disordered metabolism, suitable diet would not influence it as favorably as it usually is thought to do. The origin of gout is an interesting subject, and one which will well repay close investigation.

A WORKABLE MEDICAL ORGANIZATION.

It is safe to say, in retrospect, that a relatively small proportion of the medical men who offered their services to the Government in the recent war, entered upon their duties with any clear conception of the limitations and requirements imposed by the military establishment. It is also a fair assumption that this lack of knowledge on the part of Medical Reserve officers of the functions and actual operations of the Medical Department, as well as of military matters in general, gave rise, on divers occasions, to embarrassment and confusion on the part of doctors fresh from civilian life, and increased the difficulties under which the members of the regular establishment labored. The various medical officers' training schools organized after our entry into the war came into being presumably for the purpose, so to speak, of acclimatizing the civilian doctors to the military atmosphere.

Perhaps the doctor with an inclination in the direction of military tactics as applied to medical matters, or *vice versa*, might have encountered some difficulty in quickly enlightening himself with regard to the functions of the medical services of the Army and Navy. Undoubtedly even a "reading" knowledge thereof would have inducted him into the service with a somewhat less serious handicap than no knowledge at all. While no war ever calls forth just the same circumstances as the preceding war or wars, a knowledge of the functions of the services as exercised in other campaigns must be of value in the preparation for a coming conflict. Were it not so there would never have been recognized the need for the various histories of wars in general and of the medical aspects thereof in particu-

lar. As a concise and readily available account of the functions of the medical department in war the brochure recently brought forth under the joint authorship of two Army officers,* will prove an interesting aid to members, present or future, of the Medical Reserve Corps, and others who may wish to familiarize themselves with the duties incumbent upon the doctor metamorphosed into the soldier.

For, as the authors say, the medical department is an offensive arm of service, and as such it fights in the very forefront of the battle. Practical results and not theories are demanded. The combatant surgeon in was is "in the field, in trenches, shell holes, dugouts, in camp or bivouac, along muddy roads and in wet woods, fighting his fight along with the other combatants. He commands troops, directs transportation, organizes and controls tactical movements, supervises construction. He takes an active part in all the tactical operations of the combatant forces, accompanies them into battle, and is exposed to rifle and artillery fire, poison gas, and bombs from airplanes. He is not the swivel-chair consultant or the white-robed, steam-heated surgeon of peace." It is emphasized that he must be an administrator, an organizer, a director, a superintendent, a tactician—in short, a *soldier*. This little volume is devoted to the tactical functions of the surgeon in modern war, but it is written in an interesting manner, illuminated by numerous charts and other illustrations, and cannot fail to be of service to those in search of information concerning the active functions of the medical branch of service. It is based on the tactics of the medical service upon the organization employed during the late war, "which proved itself good and workable if not perfect."

*Medical Service in Modern War. An exposition of the Tactical Functions of the Medical Department in Campaign, by P. S. Bond, Lieutenant Colonel, U. S. Army, and C. F. Martin, Lieutenant Colonel, U. S. Army, with an Introduction by Major General M. W. Ireland, Surgeon General, U. S. Army, 1920.

KAOLIN IN THE TREATMENT OF ASIATIC CHOLERA AND INTESTINAL TOXICOSIS.

Cholera and bubonic plague are the two scourges of Asia. Although treatment of this type of cholera, true cholera, has considerably improved, especially from the preventive aspect, that is, by the introduction of improved sanitary and hygienic measures, yet an epidemic of this disease will carry off the natives of Asia by thousands when it gains a foothold. While the most effectual means of extirpating or seriously checking cholera is by the practice of efficient sanitation and hygiene, which, of course, are, as a rule, grievously lacking in those lands in which the malady is most in evidence, thereapeutic treatment is more encouraging than was formerly the case. The employment of sodium permanganate, saline injections, and the hypertonic saline remedy advocated by Sir Leonard Rogers have met with a good deal of success. As regards the last mentioned mode of treatment, it has been stated that it was successful in reducing the mortality to 22 per cent. and securing the discharge of convalescents in nine days.

At a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine, held on April 19 of this year, a paper was read by Dr. R. R. Walker on "The Action of Kaolin in Asiatic Cholera." Kaolin is a fine powder of aluminum silicate, recognized medicinally in early Roman times. It has been employed in the treatment of dysentery and sprue, also of diphtheria, when applied by insufflation to the fauces. Dr. Walker pointed out that its value in checking the course of cholera had been demonstrated by Victor Kuhn, who claimed that by effecting the elimination of cholera toxins, the use of kaolin resulted in the reduction of the mortality of the disease from 60 to 3 per cent. During the cholera outbreak in Foochow in 1919, it was used with much success. It was prescribed in suspension with an equal quantity of water and patients were encouraged to drink as much of the mixture as possible. In 30 cases so treated there had been only one death, due to puerperal complications, and convalescents had been discharged in six days. For cases admitted in a state of collapse, saline injections, administered if necessary intravenously, or continuous cupping, were advised as preliminary treatment to secure a return to consciousness. Rectal lavage was also employed. In the experience of the speaker the combined use of hypertonic saline and kaolin suspension was not as effective as the kaolin alone. After two hours' kaolin treatment all vomiting ceased, the diarrhea was checked, and in 36 hours convalescence was established. In his opinion its chief advantages were its simplicity, the cessation of loss of fluid, the early return of the urine, also its power of rapid absorption of cholera toxins, and the speedy onset of convalescence. A number of animal experiments and detailed microscopical and bacteriological examinations which had been carried out were described, some of them going to show that the cholera toxins were removed by the absorptive powers of the kaolin. As a matter of fact, the claim was made that the action of kaolin is partly mechanical in being deposited on the walls of the stomach and intestines and so acting as a filter bed, partly absorptive in removing the toxic products of the cholera vibrios. It was further noted that the amount of kaolin used in treatment was considerable, almost filling the bowel, yet it had no harmful mechanical effect, as it remained soft and pultaceous.

Walker also held that rectal lavage by kaolin suspended in water was likely to be of use in the treatment of colitis, and that general toxic conditions, for example, in dysentery, were greatly relieved by absorptive action on the bacterial products.

The number of cases treated by this remedy is not sufficient to warrant the drawing of definite conclusions, but the results so far are encouraging, and it is probable that more will be heard and learned of kaolin in the treatment of cholera and in diseases in which toxic products are formed in the alimentary tract.

Familial Arteriosclerosis and Short Life.

A case of fatal arteriosclerosis in a man aged 39 is reported by Weinfurter in the *Wiener klinische Wochenschrift* for May 19, 1921, xxxiv., 20. In regard to the familial element it is stated that the father and a brother of the patient died in the best years of manhood after the same symptoms. The patient was a distinguished mathematician, and he had always been well save that for two years before the development of his symptoms he had complained of frequent headaches. The regression of this symptom is in line with the claim that the early symptoms of cerebral arteriosclerosis may be only temporary. A fall from his horse seems to have preceded the development of the permanent symptoms, which comprised attacks of *petit mal* and frank epileptiform seizures. Lues was denied and the Wassermann reaction was negative. The urine having been found to contain albumin and casts the diagnosis of contracting kidneys was made. Intellectual disorders, as memory failure and inability to do mental work, now supervened. The author found on physical examination a blood pressure of 200, which with the urine finds seemed to justify the diagnosis of primary nephrosclerosis of the bland type. The kidneys were in too good functioning condition for the diagnosis of secondary sclerosis. The presence of beginning choked disks complicated the picture. Cerebral hemiplegia at this juncture carried the patient off. Autopsy showed a high grade cerebral arteriosclerosis which had led to regional anemia and foci of softening, this accounting for the epilepsy and other intracranial symptoms. The occupation of mathematics was believed to predispose the patient to this affection, despite the oft repeated statement that mathematics tends to conserve the cerebral functions. The kidneys were only slightly compromised and the diagnosis of a bland sclerosis was confirmed; nevertheless only the renal lesion could explain the presence of choked disks.

Primary Diphtheria of the Anus.

What is possibly the first example of this affection to be recorded in literature is to be found in *La Pediatria* for April 1, 1921, xxix, 7. The reporter is Mallardi, assistant to Professor Jemma of the University Pediatric Clinic of Naples. The patient was an infant aged twenty-two months, the child of peasants, who brought it to the clinic for a chronic condition which proved to be an association of syphilis with leishmaniasis (kala azar). It was necessary to exclude tuberculosis, typhoid and paratyphoid fevers, and Malta fever, which was done by obtaining negative tests for each of these affections. Kala azar was diagnosticated by the discovery of an abundance of Leishman bodies in a punctate from bone marrow. Both the infant and its parents gave positive Wassermann tests. The patient did well on the double specific treatment (presumably salvarsan and antimony, although details are not given). Of a sudden without apparent motive the condition took a turn for the worse which could hardly have been due to the course of the kala azar. General inspection revealed two small lesions about the anus which rapidly extended until the perianal region was transformed into a large necrotic area with a yellowish grey membrane. Examination of a loop of the secretion of the active border of the lesion showed numerous streptococci and an abundance of Klebs-Loeffler bacilli. After a single injection of 3000 Behring units of antitoxin the fever promptly fell from nearly 104° to below normal, and the local lesion also showed arrest and improvement. A second injection was sufficient. About a week was required for the healing of the wound surface, after which intravenous injections of tartar emetic were resumed for the kala azar. There is no speculation as to how the anal lesion was contracted.

Encephalitis Lethargica Grippalis.

Certain authors continue to insist on the autonomy of this affection. Thus in an article which appears in the *Schweizerische medizinische Wochenschrift* for April 28, 1921, li, 17, by Reicher, a woman assistant of Professor Sahli, on blood studies of influenza, we find a section on this disease. In the winter of 1919-20 nine patients with encephalitis lethargica were specially studied. In six of these the affection was typical, with all transitions into the myoclonic form. One of the number appeared in the midst of an attack of influenza and Pfeiffer's bacillus was found in throat smears. It was the only one of the six which showed the typical blood picture of influenza, including leucopenia. In the others there was either normal leucocyte count or leucocytosis. The same association was reported by Leichtenstern in the epidemic of 1890. The leucopenia of influenza disappears in influenza-pneumonia and if the latter be severe the leucocytosis is pronounced. Despite this fact leucocytosis is a better prognostic in influenza than leucopenia. In typical encephalitis lethargica the stronger the infection the more marked the leucocytosis. Apparently no similar case of grippal encephalitis is known at Sahli's clinic and in fact no other case is cited from any source.

News of the Week.

Tuberculosis in France.—Dr. Baillon, laureate of the Faculty of Medicine of Paris, is in this country to reveal how serious the tuberculosis peril is in France. He says that there are about 1,900,000 cases of tuberculosis in France and not more than 10,000 beds available for their care. The number of deaths has reached 20,000 a year. France lacks the most efficient weapon with which to fight tuberculosis—the sanatorium. There are no tuberculosis sanatoria in Provence, a region of a mild climate and eminently propitious for the care of the disease. It was to remedy this condition that the Franco-American Committee to Fight against Tuberculosis was created. Dr. Baillon is here to raise funds with which to complete the projected Garden City Sanatorium, in which will be treated the war victims of tuberculosis and the tuberculous children of Northern France. Dr. Baillon expresses the opinion that prohibition, if it prohibits, will go a long way toward preventing the increase of tuberculosis because in every country where alcoholism is increasing tuberculosis is increasing equally as fast.

National Red Cross Convention.—Plans for a national convention of the American Red Cross, the first of its kind ever held, were announced at the society's headquarters in Washington on July 2. The convention will be held at the Ohio State Exposition Grounds in Columbus from October 3 to 8. President Harding has agreed to address the convention if State affairs permit him to leave Washington at that time.

Attendance at Summer Military Camps Urged.—Brigadier-General Charles E. Sawyer has written a letter to State Health Commissioners asking them to encourage citizens to take the course of training offered by the Army in the Summer Military Camps, and declaring that the interest of young men in health matters will be increased by attendance at these camps. The Bureau of Public Health Service has instructed its physicians to give a free medical examination to candidates for the camps. The West Virginia Medical Association has passed a recommendation that its members make a gratuitous physical examination of men desirous of taking the training, and many members of the Medical Officers' Reserve Corps have volunteered their services for this purpose.

Professor Otto Zuckerkandl of Vienna, well known as an authority on urology, died suddenly on July 3. He had intended to take part in the International Urological Congress to be held here in September.

Provisional Health Committee of the League of Nations.—Official announcement of the membership of the Provisional Health Committee appointed by the Council of the League of Nations has been made. According to this the committee as now completed has the following membership: Dr. G. S. Buchanan, Great Britain; M. Velghe, Belgium; Prof. Madsen, Denmark; Señor Pulido, Spain; Prof. Leon Bernard, France; Dr. Charles Havelock, India; Dr. Alberto Lutrario, Italy; Dr. Yoneji Myagawa, Japan; Dr. Calmette, Morocco; Dr. Mimbela, Peru; Dr. Chodzko, Poland; Dr. Carriere, Switzerland; Dr. Luigi Carozzi, International Labor Office; Prof. Winslow, League of Red Cross Societies.

Mortality Statistics for 1920.—A recent statistical review states that St. Paul, Minn., has the lowest mortality rate of the twenty principal cities of the United States, and that Portland, Ore., runs a respectable second, the figures for these cities being respectively 10.18 and 11.20 per 1,000 population. New York City with a death rate of 12.93 stands seventh on the list. Denver with a mortality rate of 17.47 has the highest death rate of any American city. It is noted that the death rate among females is considerable below that of males. Wherever women are relatively in the majority the death rate is relatively low. Washington, D. C., has the highest death rate from typhoid fever; Cincinnati wins the prize for measles, and Rochester and Boston are tied for the top mortality rate for scarlet fever. Boston has the high death rate for whooping cough and Pittsburgh holds the record for influenza. San Francisco shows the worst rate for cancer, Newark, N. J., holds the first place so far as the number of births are concerned and New York City is a close second. In spite of the intense heat of the first week in July, New York shows the remarkably low death rate of 9.72, while Chicago shows an infant mortality rate for this week 15 per cent. higher than for the corresponding week of last year.

Medicinal Beer Permits Held Up.—Secretary Mellon announces that permits to manufacture medicinal beer will be deferred for "at least a week or two." The House bill to prohibit the sale of such beer has been favorably recommended to the Senate by the Judiciary Committee, and it will be brought up in the Senate in the near future.

Urges New Medical Degree.—A plea for the establishment by medical colleges of the degree of doctor of public health in addition to that of doctor of medicine is voiced by Assistant Surgeon-General W. T. Sedgwick of the United States Public Health Service in a lecture recently reprinted by the service. Dr. Sedgwick points out that there are forty-eight State Departments of Public Health, which require at least one hundred and fifty experts in public health and sanitary science. The United States Public Health Service finds great difficulty in getting the scores of qualified health officers that it needs. The army and navy and hundreds of counties, cities, towns, and rural districts need whole-time trained health officers. Private agencies, such as the Rockefeller Foundation and the Red Cross, cannot get a competent personnel. Doctor Sedgwick urges that the present medical curriculum should be split up at the end of the first two years. One line should remain as it is, but from it another line should branch off, which should treat of preventive medicine, vital statistics, sanitary science, laboratory methods in epidemiology, municipal sanitation, preventive hygiene, etc. The medical school which neglects this, Dr. Sedgwick says, is sending out its graduates unprepared to meet some of the most serious problems they will have to face.

The Interdepartmental Social Hygiene Board announces that a synthesis of organic compounds containing arsenic, of possible value in the treatment of syphilis of the nervous system, is being worked out under the direction of Dr. W. Lee Lewis, of the Northwestern University, and his associates. The research proposed is a part of a carefully organized plan whereby the new chemical compounds that may be synthesized through the efforts of Dr. Lewis and his associates will be tested for their therapeutic value in relation to the treatment of syphilis under Dr. A. L. Loevenhart at the University of Wisconsin.

Rockefeller Institute Announces Promotions and Appointments.—The Board of Scientific Directors of the Rockefeller Institute announces the following promotions: Dr. Frederick L. Gates, hitherto an associate in pathology and bacteriology, and Dr. Frederick S. Jones, hitherto an associate in the department of animal pathology, have been made associate members; Dr. Goronwy O. Broun, hitherto a fellow in pathology and bacteriology, has been made an assistant. The following new appointments are announced: Dr. E. V. Cowdry, associate member in pathology and bacteriology; Dr. Albert Fischer, assistant in experimental surgery; Dr. William A. Hagan, assistant in the department of animal pathology; Dr. Albert B. Hastings, assistant in chemistry; Dr. Hugh J. Morgan, assist-

ant in medicine; Dr. David I. Hitchcock, fellow in general physiology; Dr. James M. Neill, fellow in medicine. Dr. John Auer, hitherto an associate member in physiology and pharmacology, has accepted a position as professor of pharmacology at St. Louis University. Dr. Francis G. Blake, hitherto associate member in medicine, has accented a position as professor of medicine in Yale University School of Medicine. Dr. J. Harold Austin, hitherto an associate in medicine, has accepted a position as professor of research medicine in the University of Pennsylvania. Dr. Glenn E. Cullen, hitherto an associate in chemistry, has accepted a position as associate professor of research medicine at the University of Pennsylvania. Dr. William C. Stadie, hitherto an associate in medicine, has accepted a position as assistant professor in medicine at Yale University School of Medicine. Dr. Martha Wollstein, hitherto an associate in pathology and bacteriology, has accepted a position as pathologist at the Babies' Hospital, New York City. Dr. Israel J. Kligler, hitherto an associate in bacteriology, has accepted an appointment with the Zion Medical Unit in Palestine.

Plattsburg Plans Health Follow-up.—A new health examination plan is to be inaugurated at the Plattsburg Military Training Camp this summer. According to Captain Arthur F. Cosby, executive secretary of the Military Training Camps Association, there will be a complete physical examination of each man upon his arrival at camp, with notations of his physical defects. Upon his return home he will receive a report of his physical condition and will be advised what course of treatment to follow to eliminate any disabilities. In the case of the younger men the parents will be notified and army officers will keep in touch in order, if necessary, to give further advice and assistance. It is believed that by means of this follow-up system permanent results in the improved health of the men will be achieved.

Professor Lawrence Joseph Henderson of Harvard University has been appointed by the Paris Academy of Medicine as one of its foreign correspondents.

Rear Admiral William C. Braisted has resigned the presidency of the Philadelphia College of Pharmacy to take effect September 10, 1921.

Dr. William W. Leake of New Orleans, assistant surgeon of the Illinois Central Railroad Hospital since its founding has been elected superintendent of the Charity Hospital to succeed Dr. Stephen W. Stafford, resigned.

Colonel Homer Folks has been appointed by Governor Miller to succeed himself as member of the Public Health Council of New York State. The term of office is six years.

Gifts and Bequests.—The will of Henry R. C. Watson of Brandon, Vt., who died recently in Paris, bequeathes $36,250 to Roosevelt Hospital, New York, for a free memorial bed, and $33,000 to St. Luke's Hospital, New York, for a free bed.

By the will of the late Adelaide K. Carruth of Philadelphia the sum of $10,000 is bequeathed to the Philadelphia Home for Incurables.

A tract of land at Ridgeway, Pa., has been given to the Philadelphia College of Pharmacy by the H. K. Mulford Company for a botanical garden.

Medical Society Elections.—THE AMERICAN GYNECOLOGICAL SOCIETY, at its annual meeting held in Swampscott, Mass., June 2-4, 1921, elected the following officers for the ensuing year: *President*, Dr. George Gray Ward, Jr., New York; *First Vice-President*, Dr. Barton Cooke Hirst, Philadelphia; *Second Vice-President*, Dr. W. P. Manton, Detroit; *Secretary*, Dr. Arthur H. Curtis, Chicago; *Treasurer*, Dr. Brooke M. Anspach, Philadelphia; *Member of the Council for four years*, Dr. Walter W. Chipman, Montreal; *Member of the Council for one year*, Dr. Dougal Bissell, New York and Dr. Fred L. Adair, Minneapolis.

THE MEDICAL SOCIETY OF THE STATE OF NEW JERSEY, at its annual meeting held in Atlantic City, June 17, 1921, elected the following officers for the ensuing year: *President*, Dr. Henry B. Costill, Trenton; *Vice-Presidents*, Dr. James Hunter, Westville; Dr. Wells P. Eagleton, Newark; Dr. Alexander McAllister, Camden; *Corresponding Secretary*, Dr. Harry A. Stout, Wenonah; *Recording Secretary*, Dr. William J. Chandler, South Orange; *Treasurer*, Dr. Archibald Mercer, Newark.

THE OKLAHOMA MEDICAL ASSOCIATION, at its annual meeting held in McAlester, May 19, 1921, elected the following officers for the ensuing year: *President*, Dr. McLain Rogers, Clinton; *First Vice-President*, Dr. J. A. Walkers, Shawnee; *Second Vice-President*, Dr. J. C. Best, Ardmore; *Third Vice-President*, Dr. L. B. Torrence, Okmulgee; *Secretary-Treasurer*, Dr. Claude A. Thompson, Muskogee.

THE MAINE PUBLIC HEALTH ASSOCIATION, which has recently filed a certificate of incorporation, at a meeting held in Augusta, June 11, 1921, elected the following officers for the ensuing year: *President*, Dr. E. D. Merrill, Foxcroft; *First Vice-President*, Dr. Henry Richards, Gardiner; *Second Vice-President*, Dr. Sylvester J. Beach, Portland; *Third Vice-President*, Dr. F. C. Thayer, Waterville; *Secretary and Clerk*, Mrs. Howard R. Ives; *Treasurer*, Dr. Ralph Whittier, Bangor; *Executive Secretary*, Walter D. Thurber, Augusta.

Obituary Notes.—Dr. EZRA BARKER POTTER of Rochester, N. Y., first assistant superintendent of the Rochester State Hospital since 1883, died on July 24 at the age of seventy-three years. He was graduated from the University of Pennsylvania in 1872. He was a member of the American Medico-Psychological Association and the Rochester Academy of Medicine.

Dr. WILLIAM K. LOUGHRIDGE of Omaha, Neb., a graduate of Lincoln Medical College in 1894, died of kidney disease on May 24, at the age of forty-five years.

Dr. EMIL FREI, a graduate of the College of Physicians and Surgeons, New York, in 1892, died at his home in Brooklyn on June 20 after a long illness, at the age of forty-nine years.

Dr. SETH C. GORDON, a former vice-president of the American Medical Association, died at his home in Portland, Me., on June 23, at the age of ninety-one years. He was graduated from Bowdoin Medical College in 1855, and for twenty years was surgeon to the Maine General Hospital. The degree of Doctor of Laws was conferred upon him by Dartmouth College in 1905.

Dr. SARAH ELIZABETH FINCH, a graduate of

the Medical Department of Cornell University in 1904, and bacteriologist to the Skin and Cancer Hospital, New York, died from heart failure following an operation on June 21, at the age of forty years.

Dr. LYCURGUS L. STATON, a graduate of New York University Medical College in 1869, died at his home in Tarboro, N. C., on July 1, at the age of seventy-two years.

Dr. JAMES B. LATIMER of Newark, N. J., a graduate of Rush Medical College, died on June 9, at the age of sixty-eight years.

Dr. SAMUEL N. A. DOWNING, a graduate of the Denver College of Medicine in 1884, and physician of the Western Pacific Railroad during its construction, died at his home in Salt Lake City on June 19, at the age of sixty-four years.

Dr. LAMSON ALLEN of Worcester, Mass., died suddenly at Amherst College on June 22, at the age of sixty-six years. He was graduated from the New York Homeopathic Medical College and Flower Hospital in 1883. He was a member of the American Institute of Homeopathy, the American Institute of Orificial Surgeons, the Massachusetts Surgical and Gynecological Society, and the Massachusetts Homeopathic Medical Society.

Dr. LOTAN CHILSON READ, a graduate of the Cincinnati College of Medicine and Surgery in 1884, died in the Michigan Soldiers' Home, June 19, at the age of seventy-six years.

Dr. JOSEPH H. POTTS of Holyoke, Mass., a graduate of Dartmouth Medical College in 1884, died on June 16, at the age of sixty-one years.

Dr. ALFRED WALTON of Bangor, Me., died at his home on May 31, at the age of eighty-nine years. He was graduated from Bowdoin Medical College in 1867. During the Civil War he served for three years in the hospital corps.

Obituary.

WALLACE CALVIN ABBOTT, M.D.

CHICAGO, ILL.

DR. WALLACE CALVIN ABBOTT, who died at his home in Chicago on July 4, was born in Bridgewater, Vermont, October 12, 1857. His early education was obtained at preparatory schools in Vermont and at Dartmouth College. He was graduated in medicine from the University of Michigan in 1885. After graduation he removed to Chicago, where he built up a large practice on the North Side, at the same time winning many friends. He early became interested in alkaloidal therapy, and not long after his graduation established the Abbott Alkaloidal Company, now known as the Abbott Laboratories, of which firm he was president.

Doctor Abbott was coauthor, with Dr. Wm. F. Waugh, of several medical books, including "The Practice of Medicine" and "Positive Therapeutics." He was, also, editor-in-chief of *The American Journal of Clinical Medicine*. He was a member of the American Medical Association, the Illinois Medical Society, the Chicago Medical Society, the American Medical Editors' Association, the American Drug Manufacturers' Association, and the American Pharmaceutical Manufacturers' Association.

Correspondence.

TREATMENT OF DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your number of June 25 there is an article by Dr. Lester Curtis of Chicago on some cases of diphtheria with their treatment upon which the writer desires discussion.

The cases described by Dr. Curtis, who disavows opposition to antitoxin, have been treated by him since 1890, and apparently his method of treatment continues to this day. It is to be inferred that antitoxin is not being given to his patients, although it is not so definitely stated. The local use of solutions of bichloride in the treatment of diphtheria was practised many years ago at the Willard Parker Hospital in New York City both before and after the days of antitoxin, but has long since been discontinued, since no evidence of bactericidal power of the solution was forthcoming. In my opinion a hot normal saline solution introduced under low pressure into the nostrils and later into the pharynx is useful in removing membrane, mucus, pus, and broken-down tissue, and possibly in promoting restoration of the tissues to normal. Forcible injection of any solution into the nares creates the danger of introducing products of inflammation, diphtheria bacilli, and pyogenic organisms into the Eustachian tubes and setting up middle-ear disease. It is more than questionable whether bichloride solution of any strength in the presence of mucus and pus by which the bacteria are surrounded can have any pronounced bactericidal effect. Furthermore, during the time in which attempts are being made to kill diphtheria bacilli the blood of the patient is filled with toxins, constantly exercising destructive influence on the nerves and internal organs and calling for immediate neutralization by antitoxin. Whatever adjuvant treatment may seem best there is only one basic treatment for every case of diphtheria, and that is antitoxin given in sufficiently large doses and as early as possible in the disease. The physician who advocates any substitute for this treatment is trifling with human life, and the doctrines set forth by him in the medical press in my opinion are a menace to the public health.

I have written frankly in this matter, as it is a matter of some surprise to me that your columns should be open to medical suggestions which savor of a by-gone age.

M. NICOLL, JR.,
Attending Physician, Willard Parker Hospital;
Deputy Commissioner of Health.

IODINE LOCALLY IN TONSILLITIS AND DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I have just read in your June 25 number an article on the treatment of diphtheria by the use of a 1:2000 solution of bichloride of mercury by irrigation of the affected parts every two or three hours. The article is worth while reading and the treatment is worth while trying. As diphtheria is a bacterial infection of the mucous membrane of the nose

and throat, it is reasonable to believe that antiseptics that are strong enough to kill the bacteria before the tissues are invaded by them will cure or abort the disease by inhibiting the growth on the surface and preventing the formation of a false membrane. Even if such treatment does not arrest the disease at once, it prevents the extensive formation and absorption of the toxins which constitute the chief danger. About twenty-five years ago I began to treat tonsillitis by the application of tincture of iodine when the disease was just beginning, while the infection was still on the surface and had not penetrated deep down into the crypts of the gland. I found that one or two applications a day in the first day or two of the disease would often arrest its progress. It should be applied thoroughly twice a day; but when the tonsil shows symptoms of pus formation the application should be stopped as it can do no more good.

Some twenty years or more ago I was faced with a number of cases of diphtheria in one family. There were five cases in children and one in a young man of twenty years. I treated the latter with iodine; the other cases were treated with antitoxin. The young man, when I first saw him, had what promised to be a very severe type of the disease, the neck being greatly swollen; but he suffered less than the others from the symptoms of intoxication, there evidently being less absorption of poison from the throat, which was sterilized twice a day with the iodine. If the pure tincture is too strong it can be diluted to half strength.

It is a good plan to use small doses (3000 units) of antitoxin two or three times a day, for the very large doses are not needed when the iodine applications are used. I have seen some severe reactions and some deaths in diphtheria that I believe would not have occurred had not very large doses of antitoxin been given. If the tincture of iodine has been applied thoroughly, in a severe case 10,000 units may be given as an initial dose, repeated if necessary in six or eight hours. But doses of 20,000 to 50,000 units are too large and are likely to cause a severe anaphylactic reaction in individuals who are sensitive to foreign proteins.

I hope this note may lead to a more extensive use of iodine locally in various dilutions in the treatment of tonsillitis and diphtheria, applied early in the disease when the soreness first begins.

JAMES G. KENNEDY, M.D.

ELK CITY, KAN.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 15, 1921.

The Report of Viscount Cave's Committee on the Hospitals.—The long awaited report of the Parliamentary Committee under the chairmanship of Viscount Cave, appointed to investigate into and submit proposals for the financial rehabilitation of the hospitals of this country has just been published. Their main recommendations, which are on the lines foreshadowed in a previous letter, may be summarized as follows: (1) That a Hospital Commission for Great Britain should be set up by the Ministry of Health. (2) That voluntary hospital committees should be formed in each county or county borough, the King Edward's Hospital Fund to act for London. (3) That Parliament should be asked to sanction a temporary grant of £1,000,000 for 1921, to be administered by the Hospitals Commission, grants to be made normally on the recommendations of the local voluntary hospital committees. (4) That a further grant may be required in 1922, but no Government assistance should be promised beyond that year. (5) That the Hospitals Commission during the two years may recommend grants, not exceeding £250,000 in 1921-22, for extension and improvement of hospitals, subject to like contributions being made from private sources. (6) That arrangements should be negotiated through the voluntary hospitals committees for the utilization of vacant beds in poor law infirmaries. (7) That County Councils should be empowered to contribute to the expense of Voluntary Hospital Committees. (8) That failing the provision in the National Insurance Acts of a "hospital benefit," the Courts should be authorized to award to hospitals compensation under the Employers' Liability and Workmen's Compensation Acts. (9) That local authorities should be authorized to pay the cost of treatment in hospitals of persons in their employ. (10) That the payment from technical education funds of grants for the training of nurses should be considered. (11) That provision should be made for obtaining and tabulating returns of cases treated in hospitals. (12) That all contributions by employers to hospital funds should be allowed as deductions from profits for income tax purposes. (13) That where the payment to a hospital of a testamentary gift of residue is delayed for more than a year, the hospital should be authorized to claim repayment of income tax. (14) That legacy and succession duty on testamentary gifts to hospitals should be remitted.

The chief characteristic of the report is the emphasis laid by the committee on their belief in the value of the voluntary system. As for the existing financial position of the hospitals, of which it is stated there are in Great Britain 952, containing 52,194 beds, it is admitted the receipts have not fallen off, indeed they have increased; but the cost of provisions, drugs, dressings, fuel, and labor has grown to such an extent that it far more than counterbalances the increase of income. There are indications that the cost of food, drugs and dressings, which is already falling, should show a marked reduction before the end of the year; but as to fuel the position is doubtful, and it is not anticipated that there will be any substantial reduction in the cost of nursing and domestic staffs. Under these conditions it is estimated that unless some remedy is found there will be deficiencies in the present year in respect of the hospitals in the whole of Great Britain, including London, amounting to not less than £1,000,000, and this without any provision being made for the necessary extensions and improvements. The position thus disclosed appears to involve danger to the whole of the existing hospital system. Two of the large London hospitals, King's Cross and the London, have quite recently closed some of their beds owing to lack of means, and others have indicated their intention to take a similar course. And if any considerable number of hospitals should close down, the shortage of accommodation would be such that the public would be

compelled to step in and supply the deficiency, and the position of the hospitals throughout the country would be imperiled. It has been suggested that liability for the hospitals should be taken over by the state or thrown upon the rates, or at least that a regular yearly grant in aid should be made from one of these sources. In the view of the committee either proposal would be fatal to the voluntary system. The question is then asked, Is the voluntary system worth saving? The answer given is that in the opinion of the committee it is. If that system falls to the ground, hospitals must be provided by the public and the expense of so providing them would be enormous. They must then be carried on without the aid of the voluntary subscriptions and donations estimated at not less than £3,000,000 a year, and presumably without the income, about £1,000,000 a year, from endowments which were given to support voluntary hospitals only. Although convinced that state aid is imperative to save the hospitals from disaster, the committee are also firmly of opinion, first, that the assistance should be temporary only, and that it should be clearly understood that it will not be continued beyond a limited period which may be fixed at two years; and, secondly, that no grant should be made except to a hospital which is able to show that it is taking all steps which are open to it to reestablish its financial position and that it has a fair prospect of so doing before the end of the period of probation. The committee conclude as follows: In recommending some temporary assistance from public funds, it may be pointed out that the state is indebted to the voluntary hospitals for the services which they have rendered during the war in the treatment of wounded soldiers. It is true that most, if not all, voluntary hospitals which admitted military patients received a capitation grant from the War Office. But this grant in no way covered the full cost of maintenance and the Committee of King Edward's Fund informed this committee that their accountants had calculated that the aggregate War Office payments to the London hospitals alone fell short of the total cost of maintaining and treating the military patients by £530,000. It is probable that the grant suggested for 1921 will not of itself be sufficient to enable the hospitals to tide over the crisis, and that a further grant will be required in 1922. But the committee think that it should be made clear that Parliament will not consider itself under any obligation, express or implied, to continue the grant beyond the latter year, and that the responsibility for maintaining any voluntary hospital after that time will rest wholly upon those who have the charge of the institution.

International Conference on Tuberculosis in London.—The next International Conference on Tuberculosis will be held in London at the Institution of Civil Engineers, Westminster, from Tuesday, July 26, to Thursday, July 28, inclusive. The National Association, which represents Great Britain and Ireland on the Council of the International Union Against Tuberculosis, has decided to merge its Annual Conference in the International Meeting and will act as host to the International Union. The President of the International Union for the current year is Monsieur Léon Bourgeois, President of the French Senate, who will be succeeded on the occasion of the Conference in London by Professor Sir Robert Philip of Edinburgh. Addresses will be given at the opening meeting of the Conference by Monsieur Léon Bourgeois, President of the French Senate, and Colonel George Bushnell, United States Army Medical Corps. The subjects for discussion are: (1) The Modes of Diffusion of Tuberculosis Throughout the Races of the World, to be opened by Professor Calmette, Pasteur Institute, Paris. To be divided as follows: (*a*) Frequency of tuberculosis among civilized people. Its rarity among savage or nomadic races. (*b*) Number of persons infected at different ages of life in crowded centers and in rural areas. (*c*) Sources of tuberculous infection, expectoration, discharging tuberculous lesions, milk. (*d*) Contagiousness of latent lesions. Discharge of bacilli by natural excretory channels, intestine, kidney, mammary gland. (*e*) Dissemination of tuberculous infection by apparently healthy bacilli carriers. Preventive measures against the speed of infection. (2) The rôle of the medical profession in the prevention of tuberculosis, to be opened by Sir Humphry Rolleston, followed by Sir George Newman, Chief Medical Officer, Board of Education and Ministry of Health. The Right Hon. the Lord Mayor of London will give a reception in honor of the International Union, at the Mansion House, July 26. Other social functions and visits to institutions of special interest are being arranged. A fee of one guinea per representative will be charged. The secretaries are Dr. Leon Bernard, University of Paris; Sir Arthur Stanley, Chairman of Council, National Association for the Prevention of Tuberculosis; Dr. J. J. Perkins, Hon. Secretary, National Association for the Prevention of Tuberculosis, 20 Hanover Square, London, W. C.

4. The A B C of Radium. Ernest M. Daland.

2. The New Sargeant Body-Test.—George Van Ness Dearborn says that while strength and functional capacity of a part usually increases with the size of that part, those engaged in making physical measurements of men by the thousands soon learn the limitations of the information which comes from this source alone. The new Sargeant body-test may be considered as a momentary try-out of one's strength, speed, energy, and dexterity combined, and, in the writer's opinion, furnishes a fair physical test of a man and solves in a simple way his unknown equation as determined potentially by his height and weight. The new test is made by having the individual to be tested stand under a cardboard disc, or paper box cover, about twelve inches in diameter, held or suspended from ten to twenty or more inches above his head. He is then requested to bend forward, flexing the trunk, knees and ankles, and then, by a powerful jump upward, straightening the legs and spine, to try to touch the cardboard disc with the top of his head. Swinging the bent arms forward and upward at the time the legs, back and neck are extended, will be found to add to the height of the jump. When the disc has been placed at the highest point above the head that can be just touched in jumping, this height is measured. The difference between this height and the total stature is, of course, the

height actually jumped. If, then, the total weight be multiplied by the height jumped, and the product be divided by the total height of the person in inches, the result will give a fair index of the effort made in the smallest number of figures. This is an advantage in making a test and handling the data for statistical purposes. This stunt tests the muscles of the feet, calves, thighs, buttocks, back, neck, anterior deltoid, chest and biceps. These are the muscles used in all sorts of athletic sports, setting-up exercises, etc., and in the active industries. For this reason the writer believes it should precede any other all-round physical test in basic value. It is urged that the test be given a trial in order to set the actual status of this new index of personal efficiency.

1. Cooperation in Endocrinology.—J. Aug. Hammer believes that the opinion sometimes expressed that gross human morphology is a finished chapter of biology is not correct and tries to lay down some lines of advance for it in the field of endocrinology. It is not merely sufficient to establish the size of an organ—its weight. To attain a real insight into the conditions of a separate organ for the present purpose we need the most thorough morphological—numerical—analysis of it with regard to its various structural regions, if possible, right to the cellular units. We must first establish norms for the various endocrine organs. Thus, for example in the hypophysis, with accurate elimination of the connective tissue, the amount of each of the three principal portions ought to be ascertained. In the anterior portion the number of the different cell types, in the intermediate portion the number and size of the cysts with and without colloid should be approximately settled. In the thyroid the weight of the true parenchyma with deduction of the connective tissue is to be ascertained; again in the parenchyma the amounts of the trabecular and adenomatous territories, respectively, should be fixed apart from the acinar portion; and in the last mentioned part the number and part of acini with and without colloid should be calculated. In the adrenals the quantity of the cortex and the medulla, as well as the different zones of the cortex, requires to be expressed numerically. A knowledge of the approximate percentage of lipoids and adrenine in the organ would be of the greatest consequence for estimating the state of function of an individual organ. After outlining further fields for investigation in other glands of internal secretion Hammer outlines a program of work having for its aim the attainment of this knowledge. He thinks it desirable that a central body with great authority and furnished with adequate material resources should arrange for the appointment of different groups of specialists who would have to work out and test suitable numerical methods for each of the endocrine glands and who should superintend the collection of the necessary material of organs and its distribution to the various groups of workers. Our progress in endocrinology depends upon putting it in the light of the problem of constitutional anatomy in general.

4. Evolution from Status Thymicolymphaticus.—Walter Timme points out that never has any real attempt been made to trace the progress of status thymicolymphaticus through the developmental years to adult life and to mark its metamorphosed characteristics and the attempt of the individual to compensate for its disturbances. In the past ten years he has examined many hundreds of cases of status thymicolymphaticus in all stages of development including adult cases, in whom the early history gave indubitable evidence of such disturbance. The first consideration in these cases in the difficulty of adaptation to environment is the outstanding fatigue. This is due to several factors—the adrenal insufficiency, the low blood sugar content, the low alkaline reserve and low blood and pulse pressures. There is one tissue—independent of adrenalin—to increase blood pressure and sugar content, and that is the pituitary body. A study of case histories reveals two groups of status cases, one, by far the larger, in which the sella turcica on *x*-ray examination is found to be small and enclosed; and the other, in which the sella turcica is presumably normal in size and conformation. The symptomatology in the two groups is different in important particulars. In the small enclosed sella group there is always associated with the fatigue states headache. It is a headache which may be produced by any factor which will stimulate the pituitary gland. After one or two or three years of such recurring headaches, blood pressure, pulse pressure and sugar content are on a higher level, and the *x*-ray shows enlargement and erosion of the pituitary. Skeletal growth is abnormal. In other words, there is a compensatory process inaugurated automatically, which has served to overcome many of the symptoms of disability of the status case. As time progresses other symptoms of pituitary primary activity, and other glandular activity secondarily, begin to present themselves. By means of *x*-ray examinations of the chest and skull information may be obtained as to the patient's whereabouts in his progress to complete compensation. In those cases in which the sella shows much erosion with gradually increasing efficiency on the part of the patient and a diminution of headache, no treatment at all is indicated. But where the effect of compensation is not apparent, and the sella remains small and enclosed, then pituitary medication is essential.

15. The Effect of Pituitary Extract on the Rate of Urine Formation.—R. Brayer has made observations on a small series of cases which warrant the following conclusions: (1) During the first hour following the hypodermic injection of medicinal doses of pituitary extract, the urine output is markedly decreased. (2) During the same period of time the total output of urinary solids is markedly decreased, both relatively and actually. (3) During the same period of time there is a marked and constant decrease in the systolic, diastolic, and pulse pressures, and pulse rate, which decreases appear definitely related to the decrease in the fluid and solid output of the urine.

9. Hematemesis and Melena in Chronic Appendicitis.—Anthony Bassler calls attention to instances of disease of the appendix which, perhaps for toxic reasons, can cause from slight small bleedings to intermittent frank hemorrhages of alarming amounts of blood from the gastric mucosa. Such hemorrhagic condition requires appendectomy for its permanent and complete cure. In all hematemesis cases, possibility of disease of the appendix should be considered along with other factors in which bleeding of the stomach occurs. The writer has seen fifteen cases, twelve in women averaging 27 years of age, and three in men averaging 25 years of age. In all but four there was a negative appendix history, but a frank hemorrhage history. They gave no ulcer history. Disease of the appendix as the cause of the hemorrhage was judged in all; all were operated on; all had some distinctive pathologic condition of the appendix and no gastric lesions, and all at the time of operation had the pyloric blush. Not one had a hemorrhage from the stomach after the appendectomy.

10. Radium Treatment in Cancer of the Esophagus.—A. E. Rockey believes that the total number of neoplasms of the esophagus is much larger than is generally thought, and that every case of persistent difficulty in swallowing, occurring in persons of middle age, should be subjected to a careful roentgenological examination. In order to apply radium directly to a carcinoma of the esophagus he recommends the following procedure: Fifteen to twenty feet of thread are slowly swallowed. On the following day the thread is drawn up until it is quite taut and the loop of a piano wire is threaded on it and passed through the stricture while the thread is held taut. A second piano wire, carrying a rubber catheter containing radium applicators, is then threaded on the first wire and pushed into the center of the carcinoma, and the proper dose and time treatment given. This method of treatment of cancer of the esophagus requires the cooperation of the surgeon with the roentgenologist. It is the surgeon who must accept the responsibility for the correct placing of the radium applicators. This procedure, the writer believes, offers the hope that one more fateful disease may at times have a hopeful prognosis.

12. Splenectomy in Splenic Anemia and Banti's Disease.—William J. Mayo reports that 249 spleens were removed in the Mayo Clinic up to January 1, 1921, with a mortality of 10+ per cent. Of these 249 cases, 71 were for splenic anemia of unknown origin with nine deaths and 38 for splenic anemia of known origin. Sherren, Cushing and others have called attention to the fact that after removal of the spleen for splenic anemia an occasional patient has a recurrence of hemorrhage. Of this 71 patients splenectomized for splenic anemia, eight died of gastrointestinal hemorrhage during the next ten years. Other causes for which splenectomy was performed in this series of cases were chronic sepsis, splenomegaly of syphilitic origin, splenic anemia in children, and von Jaksch's disease, chronic malaria, and chronic splenomegaly. In portal cirrhosis the spleen may play an important part in the etiology and splenectomy in properly selected cases may be of great benefit. By removal of the spleen not only is toxic material cut off from the general circulation, but also the portal blood stream is reduced by the subtraction of the amount of blood poured into the portal circulation from the spleen; this relieves the hepatic cells of a sufficient overload to permit them to function normally. In performing splenectomy in the Mayo Clinic the technique of Balfour is employed.

5. Hippuric Acid Synthesis as Regards the Functional Condition of the Kidney.—P. L. Voille states that he wrote in a letter published in the *Lancet* of April 17, 1920: "Hippuric acid elimination is profoundly influenced by diet. Hence it is necessary to base a test on conditions not dependent on the intake of food." The normal amount of hippuric acid having been estimated, the patient is given a dose of 0.50 gm. of glycocol and 50 gm. of benzoic acid. From the time of taking the doses the total amount of urine is collected during twenty-four hours. The analysis should show an excess over normal of about 0.74 gm. for twenty-four hours. Since the normal output for a healthy subject is about 0.40 gm. the figures one would expect to find are somewhat as follows: 1.14 gm.—that is, 0.40 gm. for normal, and 0.74 gm., the amount synthesized from the benzoic acid and glycocol given. When the figure is lower it may be asserted that the hippuric function is abnormal, and that probably there is some renal parenchymatous disorder. Voille summarizes his work as follows: 1. The arterial hypertension is fairly closely connected with the renal condition so far as it has been possible to discover that condition by testing the hippuric acid synthesis in the cases under observation. 2. The azotemia, chloridemia, and albuminuria are evolved by crises. The modifications observed in the hippuric acid synthesis appear to be rather the reflection of functional parenchymatous disturbances that are capable of gradual modification. 3. The hepatic disturbances, since they are not accompanied by renal disturbances, fail to effect any modifications in the hippuric acid synthesis, which appears to be purely of renal origin. From the point of view of hydrology these findings may explain the results obtained in cases of arterial hypertension by means of treatments by diuretic waters which act energetically on the renal parenchyma. For instance, in the course of the Vittel treatment one frequently sees not merely a persistent lowering of the maximum tension—a result easily obtained by means of other treatments—but at the same time a simultaneous lowering of the minimum tension which alone is of any value. On the other hand, the writer has noted that diuretic waters favor the production of hippuric acid, exciting the renal parenchyma, sometimes to such an extent as to double the renal output.

6. The Evil Effects of Excess of Protein on Milk Secretion.—Gladys Annie Hartwell states that in a recently published investigation it was found that adding a quantity of caseinogen to the diet of a nursing rat caused the baby rats to die while the mother remained in apparently good health. This extraordinary result might have been due either specifically to the caseinogen, or to the fact that excessive protein was being given to the mother. To settle this point other caseinogens were substituted for the caseinogen, and in no case were the litters normal; many, if not all, of the babies died. The few which survived the lactation period were not successfully weaned, and lived only a few days after being separated from the mother. The young rats had fits, exhibited extensor and contractor spasms, and just before death extreme exhaustion was evident. Postmortem examination showed the stomach and intestines to be almost devoid of contents. The intestinal walls were thinner than in a normal animal of the same age. While it is extremely unlikely that a nursing woman ever takes a dietary containing as large a proportion of protein as was given in these experiments, if one may argue from rats to human beings, it is clear that excessive proportions of protein in the mother's diet may lead to metabolic and nervous trouble in the suckling.

6. A Path of Toxins to the Central Nervous System. Martin Button.

2. Residual Vaccines.—C. E. Jenkins describes a new technique for the detoxication of vaccines based on the principles of Thomson's method, which depends upon the fact that alkaline solutions dissolve organisms and their toxins while mineral acids precipitate the organisms but retain the toxins in solution, and upon the method of H. R. Dean, who has shown that a suspension of virulent organisms can be detoxicated by the action of eusol or hydrogen peroxide in weak solution. Residual vaccines made from a mixed suspension were used in over 200 cases of chronic bronchitis treated by different clinicians, with very satisfactory results. There have been failures, but the results on the whole have been better than if the cases had been treated with the older type of vaccine. In summarizing his investigation and results, Jenkins says it is not possible, short of gross destruction, to detoxicate completely a suspension of pathogenic bacteria. The residual toxic substance is not affected by a temperature of 120° C., it is not destroyed by weak solutions of oxidizing agents, but it is precipitated by mineral acids. It is possible to remove from a suspension of organisms all the thermolabile toxins and endotoxins. Thomson's method, Dean's method, or that of the author, are equally efficient. It is probable that the original toxic body is an integral part of the bacterial protoplasm. Residual vaccines are highly efficient therapeutic agents. They retain their maximum efficiency indefinitely. Most cases of uncomplicated chronic bronchitis respond to residual vaccines.

5. A Note on New Growth and a Reducing Substance in the Blood.—A. S. Leyton and H. G. Leyton, led by the fact that bacteria with filterable spores which can be isolated from tumors only thrive well on media containing sugar, have examined the blood sugar content of patients suffering from malignant disease and have found the reducing substances invariably increased. The picric acid method was used for testing the blood, hence the figures do not represent sugar alone, since other reducing substances may be included. Further, in most of the cases that have been under observation for any length of time a definite excretion of sugar in the urine (as tested by Nylander's fluid) has appeared from time to time. So consistent have been the results that the writers have recently felt able to rely on this test to differentiate between simple and malignant cases. They suggest to those working with simple inoculable overgrowths that they try the effect of feeding the inoculated animals on sugar.

8. Erysipelas in Childhood.—J. H. Mason analyzes fifty-three cases which were admitted to the wards of the Harriet Lane Home of the Johns Hopkins Hospital over a period of six years. They were of average severity and were selected because the observations upon them were fairly complete. A review of these cases indicates that erysipelas occurring in young children is an exceedingly serious disease, and that its danger is in direct proportion to the youth of the patient. The largest mortality occurs in the first half year of life, even when the cases of socalled erysipelas of the newborn are eliminated. The incubation period is variable; the average is about five or six days. The symptoms are those of local infection and general constitutional intoxication. Leucocytosis is a prominent feature. A low count would indicate decreased resistance. Both sexes are equally susceptible. There is probably but little difference in susceptibility between the black and white races. The negro seems to be less resistant to the infection. The disease occurs in children throughout the year, but is more frequent from October to June. The incidence of the disease depends largely upon the frequency of the presence of infection and the resistance of the patient following the initial lesion. Any form of injury which breaks the continuity of the skin may form a portal of entry. The intensity of the course of the illness is somewhat independent of the extent of the area involved and generally an advancing erythema and infiltration mean an increase in the constitutional symptoms. The duration of the disease may vary from three days to three weeks. The average is about twelve days. A fatal termination is usually the result of a general septicemia, pneumonia, or involvement of the meninges or the peritoneum. The mortality rate in the whole series was 28 per cent., including fifteen children over two years old, in whom the rate was only 6 per cent. Of the twenty cases between two and six months, twelve died, a death rate for that period of 60 per cent. The disease is best prevented by avoiding injury of the skin and in being scrupulously careful in the treatment of these injuries when they occur, and by the prevention of irritation of the skin through infectious discharges.

Long Island Medical Journal.

April, 1921, xv, 4.

1. Community Interests from the Viewpoint of the Medical Library. F. H. Garrison.
2. Gall Bladder Disease. Russell S. Fowler.

2. Gall Bladder Disease.—Russell S. Fowler, in looking over the records of his operations for gall bladder disease, finds 608 cases in which the pathology of the lesions encountered is sufficiently and definitely described to permit the division of the cases, according to the lesion, as follows:

	Total	Recovered	Died
Acute cholecystitis	230	206	24
Chronic cholecystitis	331	330	1
Acute cholecystitis and acute pancreatitis	6	4	2
Chronic cholecystitis and chronic pancreatitis	30	30	0
Carcinoma of the gall bladder or bile ducts	26	15	11
Carcinoma of the common duct and pancreas	8	5	3
Curiosities of the gall bladder—Absence of gall bladder	1	1	0
Intestinal obstruction from gallstone	3	2	1
Syphilis of gall bladder	1	1	0
Choledochus cyst	1	0	1
Ecchinococcus disease of gall ducts	1	1	0
	608	565	43

Unfortunately many medical men do not seem to grasp the necessity for an early operation in gall bladder disease, which, in view of the pathology of the disease and its proved progressive nature, the surgeon feels he may logically request. On the contrary, many cases are sent to the surgeon when the disease has

advanced to a stage where relief is possible but not complete cure. In this respect the history of appendicitis of a generation ago and of duodenal ulcer of a decade ago is being repeated. No one now thinks of any method of treatment for appendicitis other than operation, nor of treatment other than surgical for duodenal ulcer, once its chronicity is established. Yet gall bladder disease continues to be treated medically in spite of the fact of its chronic progressive nature and the well proven fact that such an infected focus is responsible for so many complications.

1. The Results of Surgical Treatment of Epithelioma of the Lip.—Walter Ellis Sistrunk made the study reported in this paper with the idea of determining the results of a number of years following operations for cancer of the lip. He recently reviewed in detail the case histories of the patients operated on in the Mayo Clinic during 1912, 1913, and 1914. Only the patients who had primary operations in the Clinic were considered, in order that the possibilities of the operation in primary cases might be ascertained. In many of these patients, however, the growth had been removed or partially destroyed on one or more occasions by the use of pastes or caustics. After dropping from the series the cases of recurrence, 178 remained. In two of these an incomplete operation was performed; that is, these two cases were, therefore, discarded from the list studied. In thirty-four cases it was impossible to obtain data after operation; these were also dropped from the list, leaving 136 cases which form the basis of the study. Review of these cases shows that the percentage of cures following operation in cases in which the glands are involved are much lower than in cases in which operation was performed before the glands became involved. The percentage of from five to eight-year cures when the glands were involved is almost identical with that obtained in cases of cancer of the breast when the glands are involved. The percentage of local recurrences seems too large. This probably could be avoided to a certain extent by a wider removal of the growth and the use of radium after operation. Rapidly growing epitheliomas, and especially those growths with a marked inflammatory reaction surrounding them, are best removed with the actual cautery without attempting to perform a plastic operation at the time. In cases in which the glands have liquefied, broken down, and extensively involved the surrounding tissues no relief can be expected. Such cases are probably best treated by means of radium and *x*-ray. Treatment of the growth by means of radium and the *x*-ray without removal of the glands does not seem a radical procedure. Patients have been seen with an extension of the malignancy later into the glands while the primary lesion remained cured. There is no doubt that radium often destroys the growth, but such a procedure is almost identical with the methods in which the growth is removed with pastes or by local excisions. Although there may be no local recurrence of the growth following the latter procedures, in about from 20 to 30 per cent. of the cases metastasis occurs later in the submaxillary and submental glands.

3. The Treatment of Acute Suppurative Pleurisy.—James Morley Hitzrot and W. M. Weeden, to determine what had been the result obtained by the routine treatment of acute suppurative pleurisies in a civil hospital service, studied the records of the First Division at the New York Hospital, and an analysis of the cases is given in this paper. The study of 111 cases is summarized: 1. In the cases of suppurative pleurisy due to the pneumococcus proper drainage instituted early and maintained long enough produced a satisfactory cure. 2. In the cases of suppurative pleurisy due to the streptococcus there were more underlying lung conditions (abscesses, etc.) which required more varied treatment, and secondary operations were more frequent. 3. The average stay in the hospital for the uncomplicated cases in this series was thirty-two days. This includes the case due to the *Bacillus typhosus*, but not the deaths, the unsatisfactory results, or the cases submitted to secondary operations.

Le Presse Médicale.

April 27, 1921, xlix, 34.

Paradoxical Hyperalbuminose in the Blood of Cancerous Subjects.—Loeper, Forestier, and Tonnet call the increased percentage in the blood of the cancerous paradoxical because it seems incompatible with the cancerous cachexia. In anemia, such as develops in the cancerous, there should be hypoalbuminosis. Again the appetite and food utilization seem to render impossible a retention or accumulation of protein. The increment stands in direct relation to the size of the tumor mass and if the growth is small the increment is small, and vice versa. A malignant growth may be likened to a hastily constructed building, erected without plans. There should be some provision for drainage, such as is seen in a physiological gland which the cancer roughly resembles. The vessels and lymphatics are very poorly constructed, and the products of disintegration readily find their way into them, giving rise to blood changes, cachexia and, of course, metastatic deposits. Comparison of cancerous growths with glands of internal secretion is difficult because of the small size of the latter. The tumor cells which gain the circulation and either dissolve in the blood, or cause mechanical embolism or actual metastases, must add their products to those of the primary growth. The normal content of blood serum in albumin is rarely more than 75 to the thousand, and the authors who have made many analyses of cancer blood have found values up to 110 per 1000—this in a tumor of the kidney which weighed almost 7 pounds. The important fact was discovered that the increase lies wholly in the blood globulin, the serin being actually diminished. The serin-globulin ratio is almost inverted in cancerous blood. The blood state is therefore a hyperglobulinosis, and the excess can only come from the tumor itself. In other words, the serin is, as one would expect, reduced, along with other blood constituents, while the tumor mass gives up globulin to the blood. The ratio of the two albumins in the tumor is 2 to 1 in favor of globulin. To use a simile, the tumor may be said to expectorate into the blood. As might be expected after ablation of a large tumor mass, the per cent. of globulin in the blood falls. Tumor albumin is toxic, while blood serum in the cancerous is not toxic. As far as is known no other affection produces this hyperglobulinosis. The authors touch on numerous other problems of serology in connection with the latter. The blood serum of the cancerous, while nontoxic, contains a peculiar erepsin-like enzyme, but this does not proceed from the tumor save incidentally. It is probably not specific and differs from an ordinary enzyme of the blood only in amount and activity of action. This is the enzyme which forms the subject of Abderhalden's studies in the field of serodiagnosis.

Cause of the Great War.—The cause of the great European war is to be sought, according to Jorge of Lisbon, in the collective psychology of the German people oriented in a morbid direction of delirium of grandeur and of persecution, of panteutonomania, etc. —*Il Policlinico.*

Book Reviews.

HYPERTHYROIDISM: MEDICAL ASPECTS. Vol. i, No. 1 of Harrower's Monographs of the Internal Secretions. Edited by HENRY R. HARROWER, M.D., F.R.S.M. (Lond.). Glendale, California: The Harrower Laboratory, 1921.

THIS monograph is the opener of a series on the internal secretions, hyperthyroidism having been selected apparently as the keynote in the harmony and dysharmony produced by the ductless glands in the human body. The amount of straight common sense displayed throughout is a relief and tends to establish confidence in the reader, who has perhaps been fed up on the wild theories and imaginative conclusions of the action of these glands drawn by the speculative members of the medical profession who have entered the endocrinological field.

"Many writers still insist that the origin of this disease remains a mystery, though to my mind toxemia —chemical, bacterial, endocrine, or emotional—is the real cause. Yet, as we shall shortly see, the complicated associated factors are the chief sources of difficulty." The paramount importance of focal infection is dwelt upon at length and the author looks to the nearest ports of entry of infection as among the most common avenues for production of this condition—the nose, throat, and head. "Acute infectious diseases are possible exciting causes of hyperthyroidism. I must call attention here to a fact which I have not seen in the voluminous literature on this subject—that in the history of the patient with hyperthyroidism, it is virtually the rule to find that in childhood, or later, the patient has suffered from whooping-cough, measles, mumps, scarlet fever, pneumonia, or other of the acute infectious diseases." We may remark, however, that it would be difficult to find an adult without some such history. The diagnosis of hyperthyroidism, clinical and laboratory tests, differential diagnosis, prognosis. general hygiene, hydrotherapy, drugs, and organotherapy form the several sections of this work. There is no drastic procedure recommended in the treatment, but, after a thorough discussion of the subject, the author offers his routine in the management of hyperthyroidism. This last chapter is more than interesting —it is well worth studying. If anyone labors under the impression that the author believes in the treatment of this condition only through the administration of certain amounts and certain combinations of ductless gland extracts, a reading of this work would be most advisable. A very complete bibliography is given.

LE FORAGE DE LA PROSTATE. MÉTHODE DE LUYS. Par le Dr. LOUIS ESCANDE. Mulhouse: A. Herbelin, 1921.

THIS brochure of 102 pages comprises the conclusions based on the experience gained in treating sixty-three cases of prostatic hypertrophy by the method of forage or canalization. The percentage of success was 90.4, and the degree of success is shown by the fact that in only one case in twenty was there residual urine after treatment, all symptoms having wholly disappeared. The tunneling process devised by Luys is the sole one which can be controlled directly by the operator's eye. The method by which the tissue is destroyed is either electrocoagulation or the galvanocautery, using Luys' direct vision cystoscope. The intervention is seemingly quite safe and as a rule does not make it necessary to intern the patient. It is conservative in the young subject, because the prostate is practically left intact; in general the ejaculatory ducts are respected and sexual relations continue to be physiological.

CLINICAL OPHTHALMOLOGY FOR THE GENERAL PRACTITIONER. By A. MAITLAND RAMSAY, M.D., Fellow of Royal Faculty of Physicians and Surgeons, Glasgow; Lecturer on Ophthalmology, University of Glasgow; Ophthalmic Surgeon, Glasgow Royal Infirmary; Author of Atlas of "External Diseases of the Eye," "Eye Injuries and Their Treatment," "Diathesis and Ocular Diseases," etc. With Foreword by Sir JAMES MACKENZIE, M.D., F.R.S. New York: Oxford University Press, American Branch, 1920.

THE science of medicine owes a debt of gratitude to Sir James Mackenzie for his endeavors to drag it back from the extremes of slipshod diagnoses and undue reliance on laboratory tests, and start it once more on the practical middle ground of dependence on the teaching of experience. It was at his suggestion that Dr. Ramsay undertook the preparation of this present work, which is so eminently practical and so plain spoken and simple that the careful reader cannot but profit by it when confronted by diseases of the eye in his practice. The title of the book expresses its scope. It deals not only with the diagnosis and treatment of ocular troubles, but also with their clinical significance in relation to systemic diseases.

In the chapter on Eye-strain the author pays a tribute to Dr. Gould of Philadelphia for "the forceful way in which he has written on the subject." He says that there is essential truth in the contention that low degrees of ametropia are responsible for headaches and many other nervous troubles, though he thinks that Gould and his followers weaken their position by underestimating the important part which other causes play in the origin of headaches, visual disturbances, and other functional nervous disorders.

The general practitioner, especially one whose practice is in a country district, where it is not easy to secure the help of a specialist, will find this book of the greatest assistance.

THE SEX-COMPLEX. A Study of the Relationships of the Internal Secretions to the Female Characteristics and Functions in Health and Disease. By W. BLAIR BELL, B.S., M.D. (Lond.), Gynæcology Surgeon to the Royal Infirmary, Liverpool; Lecturer in Clinical Gynæcology in the University of Liverpool. Second Edition. Price, $6.00. New York: William Wood & Company. 1921.

THIS second edition has been called for, since the first has been long out of print (the first being published in 1916), by the interest in the subject. Dr. Blair Bell presents his points ably and arranges them with logical clearness. With wide experience from the experimental and the clinical side, he makes a forceful argument, laying especial emphasis on the influence of the total secretions on the complex, rather than on the individual hormones. Since the first edition further research has amplified and confirmed the author's original conclusions. The author still in this edition confines to a brief space his consideration of the sexual psychoses and neuroses in woman. But his additions to the relationship and the interaction of the internal secretions between mind and body is a valuable presentation.

SURGERY, ITS PRINCIPLES AND PRACTICE. For Students and Practitioners. By ASTLEY PASTON COOPER ASHHURST, A.B., M.D., F.A.C.S. Associate in Surgery in the University of Pennsylvania; Surgeon to the Episcopal Hospital and to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases; Colonel Medical Reserve Corps, U. S. Army. Second Edition. Thoroughly Revised. With 14 Colored Plates and 1,129 Illustrations in the Text, Mostly Original. Price, $10.00. Philadelphia and New York: Lea & Febiger, 1920.

THIS is a sound conservative treatise on Surgery, constructed on the classical plan of the three divisions of General Surgery, Systemic Surgery, and Regional Surgery, and is one that can be safely recommended to one who does not look for encyclopedic treatment of the entire subject in twelve hundred pages. All the various operations are not mentioned, though in each case one or more approved operations are described or pictured. The new edition (the first appeared in 1914) is enriched with the author's war experience and that gleaned by other American and Allied surgeons and contributed to the common fund. The most important changes are in the chapters on gunshot wounds, infected wounds, shock, and reconstructive surgery. Dr. Ashhurst does not accept all the "novelties" which our men brought home from the war—for example, Willems' plan of immediate mobilization in the case of joint wounds, which he says he has never seen successful. The Carrel-Dakin dressing receives moderate commendation, though the very real danger of eating away the sutures is noted; the author evidently prefers dichloramine-T. The book is well and freely illustrated with 14 colored plates and 1,129 text figures.

CLINICAL METHODS. A Guide to the Practical Study of Medicine. By ROBERT HUTCHISON, M.D., F.R.C.P., Physician to the London Hospital, and HARRY RAINY, M.D., F.R.C.P.Ed., F.R.S.E., Physician to the Royal Infirmary, Edinburgh, with 16 Color Plates and 157 Figures in the Text. Seventh Edition, Revised Throughout. Price, $4.50. New York: Paul B. Hoeber, 1921.

THE seventh edition of a book which originally appeared in 1897 speaks well for the value attached to it by generations of medical students and their teachers. Special attention has been paid to the revision of the chapter on the examination of the heart and all has been brought to date, while the examination of the urine has had additions made and due value attached to the various processes of examination. All needed methods are included in the chapters on the eye and the nervous system, but although mention is made of radiograms in the examination of the stomach and intestines, the fact that the method of bismuth and barium meals does not fall within the scope of the book, is permitted to prevent the inclusion of valuable information as regards the margins and position of the viscera. But the book is a compend of useful information both in the wards and in the laboratory and is of handy size to carry round for study at odd moments.

SURGERY OF THE LUNGS AND PLEURA. By H. MORRISTON DAVIES, M.A., M.D., M.C. (Cantab.), F.R.S.C. (Eng.), Hon. Captain R.A.M.C. (T.) Consulting Surgeon University College Hospital, Consulting Surgeon City of London Hospital for Diseases of the Chest, Medical Superintendent Vale of Clwyd Sanatorium. Price, $10. New York: Paul B. Hoeber, 1920.

THE war added much to our knowledge regarding the surgical treatment of diseases and injuries of the chest, itself a young science in 1914, and the interest thus aroused has been maintained and furthered in this country by the excellent work done in the last three years by the American Association for Thoracic Surgery. This book should therefore be welcomed by all whose line of work lies, or is liable to lie, in this direction, and this would be the case, during peace times, especially with those whose practice is in large industrial establishments, though, of course, any surgeon may be called in occasionally to treat thoracic injuries.

The various chapters deal with the anatomy of the chest, intrapleural pressure, diagnosis and prognosis, disease of the pleura, injuries of the lungs and pleura, foreign bodies in the bronchi, gangrene and abscess, pulmonary tuberculosis, bronchiectasis, streptotrichosis of the lungs and pleura, hydatid disease of the lungs and pleural membranes, primary tumors of the lung, mediastinal dermoids, and emphysema. In intrapleural operations the author prefers the hypoatmospheric method, that is a chamber in which the air is maintained at a negative pressure while the patient breathes air at normal pressure, when it is possible to use it; but the disadvantage of size, nonportability, and expense are so great as to be prohibitive outside of a specially equipped hospital, and therefore resort must be had in most cases to hyperatmospheric pressure, but effected by means of intratrachial insufflation after the Meltzer-Auer method.

The author's style is very easy and simple, and his description of the technique in the various operations is so clear and detailed that anyone possessed of ordinary surgical experience and skill ought to be able to follow it practically. The illustrations, largely roentgenograms, are excellent, but unfortunately they are run in with the text and not printed on inset plates, necessitating the use of a highly calendered paper throughout, the glare from which is rather distressing to the eyes. The text seems to be unusually free from typographical errors. Dr. Davies has given us a good monograph, which is very valuable to the growing literature of thoracic surgery.

DIABETES. A handbook for physicians and their patients. By PHILIP HOROWITZ, M.D. Price, $2.00. New York: Paul B. Hoeber, 1920.

THE aim of the book is to effect more intelligent cooperation between doctor and patient and, while not supplanting the physician and encouraging patients to treat themselves, this being the greatest folly, it instructs patients how to prepare a varied diet on the lines laid down by the physician and also to intelligently watch results by carrying out tests which can be guarded and supplemented by the physician. For this purpose the book is simple and practical, and should be of great value to the busy practitioner. By aiding the patient to be of intelligent help, it should tend to keep the patient to his regime and thus aid in reducing the mortality of diabetes, which is one of the author's aims.

PHYSIOLOGY AND BIOCHEMISTRY IN MODERN MEDICINE. By J. J. R. MACLEOD, M.B., Professor of Physiology in the University of Toronto, Canada, formerly Professor of Physiology in the Western Reserve University, Cleveland, Ohio, assisted by ROY G. PEARCE, A. C. REDFIELD, and N. B. TAYLOR, and by others. Third edition, with 243 illustrations. Price, $11.00. St. Louis: C. V. Mosby Company, 1920.

THE fact that this is a third edition within a short period of years shows with what welcome such a volume has been received by the medical profession. It is really the standard work on the application of the principles of biochemistry and experimental pathology and physiology to clinical treatment. The authors do not propose to supplant the textbooks on physiology, biochemistry and the numerous manuals on clinical methods, but to supplement these with an application of the more recent methods of examination to diagnosis and treatment. And this they have done with thorough efficiency. In this edition the section on the nervous system has been rewritten, and an account of neuromuscular physiology is incorporated with it, by A. C. Redfield. Complete changes have been made as regards the chemistry of respiration and new chapters have been added as regards the functional capacity of the heart, the therapeutic value of oxygen, the interpretation of polysphygmograms, the capillary circulation, surgical shock, and the nature of vitamines.

In the brief space of a review it is not possible to enter on a detailed criticism as to whether all subjects are dealt with adequately or whether all are included. But it may at once be said that the vast subject is very completely treated and the book has been brought thoroughly up to date, changes in technical details having been made so as to keep the volume in as handy a bulk as possible and yet bring together the constantly increasing facts. It is the standard work on the subject, and this with later editions should be increasingly welcome.

A SYNOPSIS OF MEDICINE. By HENRY LETHEBY TIDY, M.A., M.D., B.Ch. (Oxon.), F.R.C.P. (Lond.), Assistant Physician to St. Thomas's Hospital; Physician to the Great Northern Hospital; formerly Assistant Clinical Pathologist and Medical Registrar to the London Hospital. Price, $6.50. New York: William Wood and Company, 1921.

WE have seldom seen a book so packed with information as the present volume. It is almost encyclopedic in its scope. It covers the whole field of Practice, and under the title of each disease it gives a succinct summary of the etiology, bacteriology, pathology, symptoms, signs, diagnosis, complications, sequelæ, prognosis and treatment. But it gives much more than this; for it includes special chapters on such subjects as the chemical pathology of gout, carbohydrate metabolism, etc. To give an idea of the scope of the book, it may be said that typhoid fever takes up 34 pages, tuberculosis 50 pages, syphilis 16 pages, pneumonias 22 pages. The volume contains more than any of the one volume works on Practice, and yet it is only a Synopsis. The author says that the book is for those who have to revise rapidly their knowledge of medicine in general or of some disease in particular, and for the worried student whose final examination is in sight, and for the hurried practitioner from whose ken the knowledge contained herein has long passed. For all of these readers the book should prove of service. But we would add a word of warning; it is of no use to the medical student, unless he has already studied his textbook. It is in no sense a compend, and the beginner who tries to tackle this volume will either fall asleep over it or get an acute attack of mental indigestion. The special arrangement of headings, types, and indentations is on the same plan as in the companion volume on Surgery.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-sixth Annual Meeting Held at Atlantic City, May 10 and 11, 1921.

DR. W. S. THAYER OF BALTIMORE, PRESIDENT, IN THE CHAIR.

First Day—Tuesday, May 10.

President's Address.—Dr. W. S. THAYER of Baltimore delivered this address in which he said that this year the society had sustained the loss of two of its best-known members, Surgeon General Gorgas and Dr. Meltzer. The former, born in Alabama, educated in the University of the South, graduate of Bellevue Medical School, was for forty years a surgeon in the Medical Corps of the U. S. Army. In 1901 he was sanitary officer in Havana, and applied the biological discoveries of the Yellow Fever Commission, and rid the city of that plague. The prophylactic measures inaugurated by him at Panama made the construction of the canal possible. These were two examples of the biological principles applied to public sanitation. He died in London on an important mission to Africa.

Meltzer, a physiologist, was born in Russia, and educated in Germany. He combined his daily practice as a doctor with scientific studies as a physiologist. He felt that the life blood of medical art springs from its association with the underlying sciences. Meltzer felt that to be a doctor one must be a student, a discoverer, and an investigator, contributing something to the store of knowledge, and he exemplified this principle until the day of his death at the age of 70 years. These two men, so different in many respects, represented the spirit which brought this association together on common ground. The clinician, the physiologist, the pathologist, the chemist, had here one common bond, the advancement of medicine in its broader sense. If this association continued to fulfill the conditions of its founders, it would always consist of just such a group of students representing many special interests but united in the common study of physiology, pathology, and therapy.

Report of a Case of Disseminated Subcutaneous Sporotrichosis with Lung Metastasis.—Dr. L. M. WARFIELD of Milwaukee read this paper. Cases had been few, perhaps 100 in number, reported in this country. The organism was usually saprophytic, but sometimes pathological for man. It occurred on bark, hay, decayed vegetables, etc. Four forms could be seen: (1) Localized with chancre; (2) disseminated gummata with multiple subcutaneous nodules; (3) disseminated ulcerated, with multiple lesions simulating tuberculosis or syphilis; (4) extracutaneous, in the periosteum, eye, or internal organs. Cases reported had been from unique conditions, such as bite of a hen, of a horse, of a parrot, etc. It often started with a nodule on the finger, which was disseminated by the lymph channels. In the author's case the patient, a colored man, had followed the races as a stable boy, had had venereal disease had a swelling on the top of the right foot, which broke down, and other lesions occurred, with nodules all over the body. There was a 4+ Wassermann; leucocytes, 17,000. *Treatment:* intensive administration of potassium iodide. Patient became weaker and died. *Autopsy:* Nodule in hylum of right lung, from which and from all nodules of the body cultures were made. The organism was best grown at 37.5° C.; it was pathological for white rats and rabbits. In lung conditions the organism could be found in the sputum, the lesions closely simulating those of syphilis, and were misleading on account of the giant cells. Cases were not usually fatal. The diagnosis must be correctly made and potassium iodide administered.

Secondary Mould Infections of the Lung.—Dr. CHARLES P. EMERSON of Indianapolis made this presentation. He said that penicillium infection was not supposed to be pathological, but two cases were reported as occurring in a man of 53, and a woman of 34, both treated in sanatoria for pulmonary tuberculosis. The first patient suffered tickling of the throat, sputum contained "slugs," and he had acute spells of respiratory distress and dyspnea, but no loss of weight of strength, and no fever. His appearance suggested the last stages of fibroid tuberculosis, but the sputum continually produced mycelium and the roentgenologist, without previous suggestion, diagnosed it as mould infection of the lung. The culture always gave penicillium. Put on potassium iodide, the man did fairly well, was able to work, and had but slight respiratory distress. The second patient, a woman, 34, was sent to Colorado, although she protested she always felt well. Drs. Webb and Foster saw her. Penicillium was always found in the sputum cultures. The question was whether penicillium could be a primary invader of the lung; if it were secondary, to what was it secondary? Great caution must be taken in not confusing these cases with tuberculosis, and sending the patients to sanatoria where they might be exposed to the danger of contracting that disease. In another instance two cases of sporotrichosis were reported in one family, mother and daughter. The relation to the buckwheat crop in this case could not be disregarded.

Dr. L. G. ROWNTREE of Rochester, Minn., asked if sodium iodide had any effect in these cases? There was a tremendous difference in the toxicity of potassium iodide and sodium iodide. Many syphilographers were using huge intravenous injections of the latter. Stokes, at the Mayo Clinic, used 50 c.c. of sodium iodide intravenously, so that if there were any response to this drug in this condition the large doses would be more effective.

Dr. J. B. HERRICK of Chicago asked if Dr. Emerson noted any particular features in the *x*-ray plates; if so, what were they?

Dr. GEORGE BLUMER of New Haven, Conn., asked if they used tuberculin in those cases.

Dr. T. R. BOGGS, Baltimore, said he would like to draw attention to a very important reason for non-discovery of mould infections of the lung. They had got away from studying the sputa in gross, and it was easy to overlook massive infections in sputum, when only using the ordinary staining methods with aniline dyes. The mycelium was so distorted by the heat and fixation that it was not recognizable. The spores stained imperfectly and were supposed to be large cocci. These cases must be vastly more frequent than anyone realized. The study of black and white surface on glass, use of the loop, and study of such particles on acid carbohydrate media that would restrain growth of other organisms and permit development of the fungi, were essential points. Recognition of fungus infections in the tissues was not easy by any section or fixation method. In a gland stained with eosin one might see no evidence of mycelia, although there were many. One must pay special attention to the methods of demonstrating these infections, and must look to the bacteriologist for some serious effort to standardize the present chaotic descriptions of these organisms. Medical men did not know how to describe them technically, so that it was a matter of great difficulty, in cultivating a study of the biology of moulds, to say to which group they belonged. One must look to trained men to help one to talk intelligently about these organisms.

Dr. S. SOLIS-COHEN of Philadelphia said that in carrying out the statements of the last speaker in regard to laboratory methods, in many laboratories no matter what the sputum was sent in for, one got back the same answer: "No T. B." If the laboratory technicians were sometimes interested in what was present as well as what was absent, they might sometimes give a report: "Unknown organism." Something more than the ability to fix a culture or to stain a slide was necessary to be a technician.

Dr. W. S. THAYER of Baltimore said he had two instances of sporotrichosis under observation, which he had intended to present last year, and had not yet prepared the cases for publication. A woman came to the hospital in the fall of 1916, presenting a picture of bronchial and peribronchial obstruction and great dyspnea. They thought it was aneurysm. She showed induration at the roots of both lungs, but nothing definite in the sputum. No lues, although there was a 4+ Wassermann. She was sent to Asheville, and Dr. Miner

said it was not tuberculosis but probably due to mould infection. She returned to her physicians and was put under vigorous antiluetic treatment with arsphenamine. On return from the war the speaker found her specimens in the laboratory. The lungs showed extensive areas of firm, slaty color, and so much sclerosis that it seemed as if the bronchi were grasped in a vise. In the tissue was found the sporotrichum; it was cultivated, but the group was not determined. In the hospital examination of the fresh sputum was neglected, which was just as important as examination of fresh blood, and neglect of this point accounted for failure to recognize cases. In another case, the man showed acute respiratory infection, with some remarkable subcutaneous nodules, like lipomata, and afterward seeming like subcutaneous gummata. They suspected sporotrichosis. It was not lues. He had been treated well with iodide of potassium and was better, but they were not encouraged with the prognosis.

Dr. CHARLES P. EMERSON, in closing, said in answer to Dr. Rowntree's remark, that potassium, not sodium iodide, was used. The *x*-ray picture was quite different from that of the tuberculous lesion, which was more pronounced at the upper lobe, and had longer markings with anastomoses. With the other we had no evidence of calcification near the hyla, and little flocculent shadows scattered around. The roentgenologists, without knowing it was mould infection, or having it suggested to them, pronounced it as such. In answer to Dr. Blumer, they did not use tuberculin, for the diagnosis of tuberculosis based on the subcutaneous or conjunctival test was difficult in adults, and by elaborating the technique of the complement fixation test in tuberculosis they arrived at a fairly accurate point. Aspergillus had been found and penicillium also. There were many infections that were not aspergillum. Were they penicillium? Were they mucori? Did they come from the trachea?

On Experiments in Epidemiology.—Drs. SIMON FLEXNER and H. L. AMOSS of New York City made this presentation. These studies had consisted of artificial control by a prearranged plan of epizootic outbreaks. These were considered as epidemics. The organism used was *B. typhi murium* which produced epidemics among mice. The mice were assembled to represent a village. One hundred normal mice, free from *B. typhi murium*, were put in twenty cages. Ten mice were then fed a heavy suspension of the organism, and were put among the hundred normals. Feeding and cleaning were done in one direction by one attendant, but it was found that the epidemic did not progress in the line of feeding. Roaches and flies were eliminated. Eight of the ten infected mice came down, and seven of the normal mice, by contact. After thirty days, another series of mice was brought in. Those previously exposed and the new ones were watched and the epidemic progressed in a series of waves, the crests of which became smaller. Among the first exposed the deaths were higher and more frequent. After two weeks there were no more deaths, and the mice were stocked up to 300 again. The mortality now was 68 per cent. Originally it was 58 per cent. They were again restocked, and the mortality now was 14 per cent. It was supposed that greater mortality would occur among new arrivals, but it was about the same among old and new. The number of carriers was found to be in inverse proportion to the death rate—the higher the death rate, the fewer carriers. The carriers had agglutinins in the blood, but these were not protective against a new epidemic wave. The strains of organisms had different virulence at different heights of the disease. One was tempted to interpret these facts, but there would be less cause for regret if the men drew their own conclusions.

Dr. FLEXNER said they had been greatly impressed with waves of epidemics in this country, such as poliomyelitis, influenza, and, lately, epidemic encephalitis. The study of these waves had been restricted to statistical data from human beings. At the Rockefeller Institute there was a very violent epidemic of typhoid in the cancer breeding mouse stock, which was a separate stock. They sought experimental light on the epidemic and on the curves of epidemics as ordinarily produced. They were extending this study to one of respiratory infection in rabbits, commonly called "snuffles," to be reported on later. These two studies would cover epidemics of gastrointestinal infection and respiratory infection. The facts elicited were very interesting, especially as regards the introduction of normal mice among the population which had successfully passed through the epidemic. Dr. Topley of London had also undertaken a similar study, with which there was a general coincidence. These studies differed from those carried on among human beings in that they dealt with mortality entirely, while human studies dealt only with morbidity. One could not draw exact parallels between this and human infection, but they could be compared with mortality statistics. The striking thing was the wave incidence even when measured entirely by mortality. It was thought wise to present these studies at this juncture, because they expected to go on for many years and study different phases, hoping to acquire data referring to the sources and causes of epidemics.

Remarks Upon the Symptomatic Treatment of Pneumonia.—Drs. JAMES H. MEANS and A. L. BARACH of Baltimore presented this communication. To apply correctly a specific therapy in pneumonia one must visualize the morbid anatomy and functional pathology. In analyzing pneumonia, one saw in it a respiratory battle. Dyspnea would arise when the demand for ventilation was greater than the supply. Several factors called for greater ventilation: (1) metabolism was increased; (2) acidosis was often present; with nonvolatile acid in the blood the carbondioxide must be kept lower; (3) there was anoxemia; (4) deficiency of blood flow, which must be compensated by hyperventilation of the lungs; the enlargement of the heart in these cases was perhaps explained by the asphyxia; (5) marked reduction of the vital capacity of the patient because part of the lung was consolidated; (6) abdominal distention might be present, limiting the respiratory excursion and causing rapid shallow breathing, the most expensive for the organism as it required more work and increased anoxemia. There were two ways of combating these symptoms, one could reduce the demand, or increase the supply of ventilation: (1) one could alter metabolism and correct acidosis by giving alkali to ensure normal hydrogen concentration of the blood. Sodium carbonate could be used, even if there were no free carbonic acid, because alkali tolerance was increased in pneumonia; (2) oxygen therapy could be used to improve the blood flow, especially in anoxemia; (3) we could remove abdominal distention and improve the pulmonary bellows. The correction of acidosis and anoxemia would improve the chances of recovery by leaving the patient free to combat the infection.

Dr. G. M. KOBER of Washington, D. C., said he had greatly enjoyed Dr. Means' excellent contribution to the symptomatic treatment of pneumonia. He desired to recall the socalled eliminative treatment advocated by Hugh Bennett in his classical lectures over fifty years ago. This treatment consisted in the administration of tablespoonful doses of a mixture composed of liquor ammonii acetatis, ʒvii; spiritus ætheris nitrosi, ʒi; repeated two or three hours, until diaphoresis set in, then the intervals were lengthened. In the light of modern pathology, these diaphoretic and diuretic agents evidently subserved a useful purpose in the elimination of toxins, and the blood being determined more or less to the periphery it had also a beneficial effect on the heart and lungs. He had resorted to this treatment ever since and had observed its good effect at the Carlisle Cavalry Recruiting Depot in 1868. It appeared to prevent the development, in all but bad chronic heart cases, of the dangerous symptoms such as demanded the administration of oxygen.

Dr. C. F. HOOVER of Cleveland, O., said that in regard to the source of anoxemia and the relation between anoxemia and air hunger, the latter term described the sensations of the patient. The patient could have extensive pneumonia with pronounced cyanosis but have no air hunger, although he might have hyperpnea. This did not come into the field of consciousness of the patient as air hunger. In a man with complete consolidation of the entire right lung, there was no non-saturation of the lung, and no anoxemia of the aortic blood. This man had a tuberculosis pneumonia and showed a pale, ischemic lung. A pneu-

mococcus patient with cyanosis and anoxemia had a red hyperemic lung, therefore it was due to the unrespired blood from the lung to the aortic stream. In the ischemic lung there was no unrespired blood contributed to the aortic stream. Two patients were seen with arteriovenous aneurysm, and the heart became enlarged with the minute flow of blood to the heart; as in Basedow's disease, there was an increased burden on the heart without increase in the capillaries. Patients with arteriovenous aneurysm had enlarged ventricles, but the auricles were not enlarged. When dealing with a large heart in pneumonia, one must determine whether it was a compensatory measure or increase of the minute flow of blood; if the former, there would be enlarged right auricle. If there were no auricular enlargement one should not give digitalis.

Dr. S. SOLIS-COHEN of Philadelphia said that these careful and scientific studies bore out the clinical experience of many years. One physician at Atlantic City had used sodium bicarbonate as a specific in pneumonia. Maintaining the alkalinity of the urine was a clinical practice capable of being carried out by the nurse or by intelligent members of the family. As a rule of thumb it answered the purpose; and with a continuous administration of alkali one could use any alkaline diuretic. The use of oxygen had gone through many successive waves of acceptance and rejection. Oxygen must be administered in a proper way so that the patient really got it; it would not revive the dead. If the patient really got it, it was a life-saving measure. If used as a routine measure, it would waste a lot of oxygen, but would save life. Another important question was that of abdominal distention. Lavage and the administration of pituitrin, guided by the systolic blood pressure, tended to prevent gastric and abdominal distention.

A Case of Alkaptonuria with a Study of Its Metabolism.—Drs. C. P. HOWARD and R. H. GIBSON of Iowa City reported this case. The patient, male, had symptoms of brain lesion, probably tuberculoma. The urine showed a reducing body. The specimen showed dark brown pigment, recognized as alkapton, and he was transferred to the metabolism ward. This pigment was hydroquinone acetic acid. Twelve cases had been reported in America. They were familial, but not congenital. Often they occurred in children of consanguinous marriages, when the parents were cousins. There were few symptoms. The patient would apply for life insurance and be rejected as a diabetic. Rarely ochronosis occurred. An inborn error of metabolism was the cause of the disease. Protein diet increased it. The change probably took place in the body tissues. There was disturbance in the conversion of phenylin or tyrosin into homogenistic acid, and acetone was produced. In this patient the nitrogen ratio was studied and there was a rather high nitrogen retention. The sulphur production was normal.

Dr. T. B. FUTCHER of Baltimore said Dr. Howard had mentioned the rarity of this condition and had spoken of the relationship of this metabolic disturbance to ochronosis (which meant ochre-colored cartilages). He had reported alkaptonuria with ochronosis in a case in which the cartilages of the ears, finger nails, and cheeks had this peculiar slate color. There were three cases in that family. Osler used to speak of arthritic changes in the first patient, and there was distinct crepitation of the joints on palpation.

The Bearing of the Evolution of the Pneumonic Exudate on Local Chemical Factors Influencing Recovery and Resolution in Lobar Pneumonia.—Dr. FREDERICK T. LORD of Boston presented this communication. He said that he did not want to neglect the humoral aspects of recovery from pneumonia, such as the matter of agglutination of serum, which had been proven by Cole and by Cecil, but there were aspects of humoral immunity which were difficult of comprehension. They checked septicemia, but why did pneumonic patients have involvement of successive lobes? Why did they have relapses? Why did the pneumococcus grow readily in pneumonic and postpneumonic serum. There might be local aspects of recovery. This matter was not proven, but it was suggestive. Partial isolation of the lung was important. The pneumonic process went through a certain evolution. There was increased serum at first, and later increased hydrogen-ion concentration of the pneumonic lung. The organism might be killed by the hydrogen-ion concentration, but also, as in the test tube, addition of serum might prolong the life of the organism. Diminution of serum and increased acid could achieve the death point of the organism. The hydrogen-ion concentration was important to enzyme action in general. There was a serum and enzyme balance, which probably protected the framework of the lung. When diminution of serum occurred there was setting free of the enzyme, which split up through the amino acid nitrogen. The lung was spared by the antiferment in the capillary circulation. Delayed resolution was caused by too little enzyme, or too much serum.

Dr. T. SOLLMAN of Cleveland, Ohio, asked if there was any evidence that the acidity took place during life, or was it a postmortem change?

Dr. LORD said they had no evidence that acid formation took place during life. They tried to obtain this evidence, but it was impossible to be sure. They had determined the increase of acid in the lung immediately after death. Of course it might be formed postmortem; one could not exclude that possibility.

Observations on the Bactericidal Activity Against Bacillus Diphtheriæ of the Whole, Coagulable Blood of Immunized Animals.—Dr. S. SOLIS-COHEN of Philadelphia and MEYER SOLIS-COHEN presented this paper. They said that Dr. Heist had shown that there resided in the blood of animals a property inimical to the growth of organisms to which the animal was immune. That was confirmed by Kohler. This substance was present in the whole, coagulable blood of the immune animal; it was not demonstrable in serum, in defibrinated blood, or in citrated blood. When injected to cause artificial immunization the same property appeared in the immunized animal. Two measurements were used: (1) the time at which the organism was killed in the tested blood; (2) the dilution of culture in which growth could be proven. Diphtheria presented a different problem. The immunity was found to be antitoxic, not antibacterial. Two points were discovered: (1) bactericidal power against *B. diphtheriæ* was found in the blood of the rat; (2) in human beings subjected to the Schick test, in some there was bactericidal power, but there was no correspondence between immunity by the Schick test and the bactericidal power. Dr. Park thought the recovery from diphtheria was by the production of bactericidal substance, not by antitoxin, as those recovering had a positive Schick. The horse was tested to see if the bactericidal power corresponded to the antitoxic immunity. The antitoxic power in the blood was due to antitoxic immunity and bactericidal substances were not necessarily increased. In rabbits bactericidal power could be induced. They would see if high bactericidal power would cause high induced resistance, as in pneumonic infection.

Dr. WILLIAM H. PARK of New York said that there might have been an error in thinking that antitoxin immunity effected a cure. They found children without antitoxin in whom antitoxin did not occur at all until weeks after the recovery, so probably bactericidal immunity caused recovery. Dr. Cohen would have to work very accurately, as he was in a very difficult field. Bactericidal values for one thing were not the same for another. There was no reason to fear that a single antitoxin would not apply to all types of cases.

Dr. SOLIS-COHEN, in closing, said he and all who were working with him were fully alive to the questions raised by Dr. Park. They did not observe any differences in growth between the toxin and nontoxin producing varieties, but more recent work by the Philadelphia Board of Health had found three types which could be distinguished. Perhaps the strains produced in New York should be called small toxin producers or nontoxin producers. There were some Klebs-Loeffler bacilli which were killed in a very short time by the blood, while other groups required a long time or were not killed at all. They fully realized now that they had got into very deep water and would be glad if some other workers with better laboratory facilities would take up the study and push it.

Yaws: An Analysis of 1,046 Cases.—Drs. W. L.

Moss and H. G. Bigelow of Baltimore presented this study of cases in Santo Domingo. Yaws was also called bubo and frambesia. Its distribution was throughout the tropical world. Some workers considered it identical with syphilis, but there was a distinct etiology, as syphilis could also develop in a yaws patient. The disease was due to *Treponema pertenue;* it had primary, secondary, and tertiary stages, but they were not so clearly defined as in syphilis, and were apt to overlap. Primary stage: two to four weeks' incubation, with malaise, pains, headache, fever; there was a papule with yellow secretion, a crust formed and fell off, leaving an ulcer. Secondary stage: one to three months after the primary; generalized eruption of granulomata with systemic symptoms, which persisted three to six months or a year; the scabs fell off, leaving pigmented scars. Tertiary stage: this might occur years after the secondary; there were gummata and ulcers leaving large scars; bone lesions were common. Mortality was low. Treatment: administration of potassium iodide and sodium bicarbonate. Neosalvarsan in two or three doses effected a cure in many cases. Ages of patients varied from one month to sixty years. The initial lesion was usually extragenital, in contrast to that of syphilis, and 25 per cent. occurred in patients under five, so that no amount of sexual precocity would account for this early occurrence if it were venereal in nature. It might be transmitted by some insect. The mucocutaneous or moist surfaces were chiefly affected.

Dr. E. J. Wood of Wilmington, N. C., said yaws was described by Bricknell in the "Natural History of North Carolina." Many cases of the disease occurred among white children, and there was a large percentage of positive Wassermann reactions among these cases, which might possibly be accounted for by the presence of yaws, and by the small proportion of vascular and nervous lesions that negroes suffered. All Southern physicians would be deeply indebted for this contribution.

Dr. S. Solis Cohen of Philadelphia said he would like to ask Dr. Moss about the treatment.

Dr. W. Riesman of Philadelphia said there was one case in the Philadelphia Hospital—a white soldier who had picked it up in France. He had a strongly positive Wassermann. Dr. Moss did not refer to this feature.

Dr. J. Collins of New York asked Dr. Moss if he had the opportunity to investigate any of the terminal cases from the pathological standpoint to see if the lesions were in the peripheral nerves and the muscle substance, and not in the spinal cord. That would make an important differentiation from syphilis, because syphilis very rarely produced the former lesions.

Dr. Moss, in closing, said they used neosalvarsan, 0.6 gram dosage, diminished in proportion for children. Observations were made on the result of treatment in 593 cases, and were tabulated according to the number of injections: one injection, 30 cured; two injections, 53 cured; one to three injections, 14 cured; four injections, one cured. Altogether 16.5 per cent. of the cases were cured, every manifestation of the disease having disappeared; 15.5 per cent. were considered unimproved. They took the Wassermann in a limited number of cases and of these it was positive in 85.7 per cent., and negative in 8 per cent. As to the differentiation between yaws and syphilis on the evidence they were able to obtain, namely, the statements of the patients who were acquainted with both diseases and knew the difference as regards manifestations: (1) patients said they had yaws; (2) denied syphilis; (3) patients knew the location of the primary lesion; (4) the primary lesions were not the same as in syphilis; (5) it did not resemble chancre and was usually extragenital; (6) the generalized eruption did not resemble syphilis, and there were no mucous patches or alopecia. The response to salvarsan was conclusive.

Plaguelike Infections.—Drs. Richard P. Strong and W. T. Councilman of Boston read this paper. Examination of 10,000 rats per 100,000 inhabitants was considered sufficient to obtain evidence of the plague. The rat served as the basis of investigation. Plaguelike organisms, resembling *B. pestis,* were found in rats; these included (1) the group of hemolytic septicemic organisms affecting chickens, rabbits, swine; (2) pseudotuberculosis; (3) typhoid organisms, as *B. typhi murium* and the hog cholera bacillus. One organism that was pathological for animals was *B. towlourense,* a very minute, round or rod-shaped organism, which caused necrosis and proliferation of the vascular endothelium, causing congestion of the large lymphatics. Autopsy showed rigor mortis and a granular surface of the liver, like pepper grains. This was so characteristic that with the naked eye one could distinguish the lesions of *B. towlourense* from those of *B. pestis.* The British Plague Commission emphasized the importance of making the correct differential diagnosis.

Dr. W. W. Ford of Baltimore said there was one case seen of a colored man, who came in complaining of very severe fever; on examination the temperature was 104°. There was no evidence of venereal infection, but he gave an obscure history of syphilis ten or twelve years previously. There was very marked enlargement of the inguinal and axillary glands. The picture was suggestive of bubonic plague. The material aspirated from the glands gave cultural reactions which seemed to be those of *B. pestis.* They were puzzled what to do. The man had been a dock laborer and presumably had been exposed to rat bites. McCoy decided it was not plague, on the basis of the lack of virulence for animals. They thought it was a nonvirulent plague organism. In cases of this character what should one do? One must establish a diagnosis at the time of occurrence. From the standpoint of politics one should hesitate to report it as plague, one might set up international complications. The case was observed for a long time, and the man recovered spontaneously. He did not have plague. This showed what difficult questions arose in regard to plague. We were at the beginning of the study of plague and plaguelike organisms in this country.

Dr. H. Noguchi of New York City asked if this was a direct contact infection. The organism was one-fifth of a micron in size. Would it assume a form which would pass through an ordinary filter?

Dr. R. P. Strong said they did not know anything about the mode of infection in this case. Dr. McCoy found that the organism would not pass through the Berkefeld filter.

Dr. William H. Park of New York City said that Dr. Ford had suggested a question whether it would be wise to send on the culture to Washington. One could easily stir up trouble for the health departments. In New York City they had not had a case of plague in thirty years. They had had a few cases in the harbor. They kept on examining rats and this cost a good deal of labor. In summer time the rats were partially decomposed, and it was very nauseating work for the laboratory workers. They had examined several thousand and had never found a plague bacillus. A few thousand would be enough. Rats were found with plague before human beings contracted it. This amount of examination took the public health worker's time from more important things. The health department had seven rat catchers at work and it kept the department busy.

Dr. Strong, in closing, said that when in doubt one should always send to Washington. He thought a few examinations carefully made would be worth more than a great many. The examination would be of no value on decomposed bodies.

Etiology of Infectious and Parasitic Diseases.—Dr. Theobald Smith of Princeton, N. J., opened this discussion, saying that etiology was the study of the entire field of medicine from a special point of view. If one could comprehend the cause one could intercept it. Observation of causes must be associated with experiment. Nature was continually experimenting and observation was taking notes. To interpret correctly one must, as far as possible, reproduce natural phenomena. They had reached a stage when the conditions influencing disease could be accurately measured. There were three factors: (1) heredity; (2) environment; (3) parasitism. These three factors reacted on each other, and the animal body reacted on them. In parasitism there were two bodies reacting on each other. The unicellular organism used to be considered the beginning and end of disease; now it was known that immunological reactions of the host played an important part. The study of epidemiology from a bio-

logical standpoint would help in clearing up causes and would show what were the influences besides the infective agent. The formidableness of the invader was due to its power of multiplication in the host. Some were adapted to one host only, others led a saprophytic existence, or became saprophytes. The smallpox parasite was specialized for one host. Other organisms were predatory, others were surface parasites. Four conditions were essential: (1) entry; (2) multiplication; (3) escape; (4) transfer to another host. Infective parasites left the body in armies, but few entered. Penetration into the normal body was unknown, and traumatism must play a part in making tissues vulnerable. Multiplication and escape were also essential to the parasite. Superficial tissues allowed of ready escape, but deep tissues were unnecessary to the organism, as they did not provide escape. Comparative pathology would fill many gaps in the knowledge of parasitism; the study of primitive man and of animals would reveal underlying, unifying factors dealing with infection and immunity.

Dr. A. R. DOCHEZ of Baltimore said that infectious diseases had reached a fairly stable state, and further modification did not seem likely, as few diseases had died out, and no new ones were added. Some species of bacteria had become saprophytic. Some parasites, such as *B. coli* and *B. tetani*, had found favorable conditions and had become specialized. Why did not all parasites reach such a stage? Was there any change in the suitability of the host? Each group seemed to have a pathological member which caused disease, and the pathogens had often to be tested by immune reactions to distinguish them. As the organism became a permanent parasite the resistance of the host rose. The pneumonia organism was the same all over the world, except in South Africa, where the species affecting the negroes was more virulent, probably having found a fertile soil. The organism had taken advantage and had become established as a parasite. There was a struggle between organism and host, the former having power to multiply and invade the tissues, and some organisms possessed toxins to break down the cells of the host. Animal passage increased the virulence of organisms, but when very virulent they destroyed the host and with it themselves. Often the ground was prepared by a primary virus before they could manifest their activities. This was seen in the war, when virulence was high on account of passage from individual to individual of measles and pneumonia, and also in the recent influenza epidemic. Three factors might account for this: (1) increase of the power of the parasite; (2) decrease of power of the host; (3) favoring circumstances which altered environment. In regard to epidemiology there were two or three factors: (1) infection in a fixed population tended to disappear; (2) continuous addition of new susceptible material prolonged the period of infectivity because the introduction of new material gave the parasite a chance to freshen up its invasive powers. The study of the effect of the organism on the host would answer the question whether some were primary invaders or were dependent on others.

Dr. HANS ZINSSER of New York presented the final paper on this topic. He said that the correlation of the enormous material available was the next step in the work of the immediate future. In the study of immunological processes he had taken up particularly that of antigens and antibodies. In regard to the phenomenon called hypersensitiveness and the study of exotoxins and endotoxins he found products which appeared early in the cultures. There were two types of skin reactions: (1) sensitiveness to horse serum, developing early and passing quickly; (2) the skin reaction primarily associated with infection, a later reaction with necrosis. This applied to guinea pigs and to man. Did either of these reactions correspond to anaphylaxis? The skin reaction to horse serum was parallel with the general development of anaphylaxis, but the tuberculin reaction in guinea pigs was different. Both reactions could be seen in the same animal, but independent of each other. Typhoidin and mallein reactions were infective. He worked with human serum, adding acetic acid to the precipitate, and called this nucleoprotein. When boiled it gave albumins and globulins which, if boiled again, produced something which acted like Bence Jones protein. (He would not say it was that, because there were a good many chemists there.) There was a clear solution left, which he called proteose. This gave the deep-seated reaction, nonprotein in nature. The uterus of the tuberculous guinea pig would not give reaction to the proteose fraction. The question was, was this proteose an antigen, that is, did it produce antibodies? He believed there were two antigens, one a typical antibody producer; the other, proteose, producing antibody with difficulty. The question was why should the infective reaction be superficial and apparently vascular and the proteose be a deep seated reaction? Bacteria that gave skin reactions passed out a proteose-like substance which caused sensitization. This was probably the important antigenic substance during the infection. The method of sensitization was different in time and quantity from the true proteose. Why did this not form antibodies as easily as the whole protein? As the substances became more and more diffusible they did not have to produce antibodies. The whole protein had to produce antibodies. One antigen was supposed to react with several antibodies, but the antibodies might be identical. Where one worked with a single chemically pure antigen one antibody would be produced. The uniting of antibody and antigen would change the antigen. Agglutination and precipitation were secondary phenomena which took place after union of antigen and antibody. Agglutinins and precipitins might be identical, and only different stages of the same phenomena. If one considered all the antibody effects as due to the same substance one would have a simplification of the views on antibodies. If one could recognize that the infection of the animal was not purely by a protein body, but there was also a proteose-like substance which might enter the body by its greater diffusibility and become toxic, because of the sensitization, this unifying concept of antibodies would simplify the work and give a new starting point from which to investigate these phenomena.

Dr. SIMON FLEXNER of New York said that anyone who had attempted to unravel some of these phenomena was impressed by their complexity, but they were moving in the direction of getting material which could be handled more effectively. There were two or three essential points: Ethnologists were getting concerned lest pretty soon they would be out of a job. So few primitive peoples were left to study that material dealing with primitive civilizations was scarce. To simplify some of the problems one must go to the regions where certain diseases were being produced, and determine what the reaction was between parasite and host rather than introduce the complication which existed in the operations of parasites among hosts among which they had flourished for centuries. The most valuable material being collected was that arising from the study of the incidence and morbidity of tuberculosis, as, for example, among African troops, exposed for the first time among Europeans. Measles introduced into the Fiji Islands was as destructive as the plague among those nations, so that one could secure experimental data still, in the study of parasitism in new populations. That was what Dr. Dochez referred to in pneumonia, the rise in virulence in individuals hitherto unexposed to pneumococci. Another question was the related study as to what were primary and what were secondary agents from the parasitic standpoint. There was the question of pneumonia following measles. That could be studied experimentally.

Dr. EMANUEL LIBMAN of New York said Dr. Olitsky had made some very interesting studies. He caused lesions with the virus of the influenza organism, such as edema, hemorrhage, and emphysema. Dr. Baer found the same organism in the lungs of animals injected by them. There was a blood thrombosis in the capillaries and small arteries. The lesions began around these vessels in the lung parenchyma and walls of the trachea which was responsible for the ease of introduction of the organism in pneumonia. The effect was on the blood vessels and hematopoietic organs. Another question was that during the epidemic a number of people got infected without showing evidence of disease. In the course of work on typhus fever by Drs. Baer and Olitsky, with *B. typhi exanthematici*, they found that the complement fixation test against that

organism was never positive in 200 controls and positive only in typhus fever. The agglutination was negative in the controls and positive in patients at the crisis. Dr. Baer examined his own blood and found a 4+ complement fixation against this organism. He had not been well and thought he had had a mild attack; the reactions disappeared in a certain time. In animals he found the same thing. Contacts had reactions against the organisms while controls were negative. In Russia, at a time when there were 28 cases in contact, 13 out of these developed reactions against this organism. Whether one believed this organism was the cause of typhus or not, it was certain that one got no reactions except in contacts with typhus. Complement fixation test and agglutination did not necessarily mean immunity. Contacts could be infected with the virus without getting large doses.

The Pathology and Etiology of Typhus Fever.—Dr. S. B. WOLBACH of Boston presented this paper. The work was carried out under the auspices of the Red Cross Societies, and lice feeding on typhus patients were studied. It was possible only to infect a small number of lice from the patient. Inseparable from the infection was the finding of minute filamentous bodies in the gastrointestinal tract of lice. These stained by Giemsa were nonmotile, and could not be cultivated. The general evidence of infection consisted in finding bodies consistent with Rickettsia in experimental lesions. The lesions caused by typhus virus were vascular, with proliferation of the endothelium of the vessels. This explained the lesions in the central nervous system. There was reaction of the neuroglia and small nodules were formed throughout the central nervous system. The manifestations depended on the distribution of these nodules. Coma, delirium and death occurred with extensive involvement, according to whether the lesion was located in the midbrain, medulla, or cortex. Rickettsia organisms had been found in trench fever, as well as in typhus, but they were larger, extracellular, and stained more deeply with Giemsa.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CONNECTICUT MEDICAL EXAMINING BOARD.

November 9 and 10, 1920.

(*Concluded from page 1079.*)

OBSTETRICS AND GYNECOLOGY.

1. Give varieties of mastitis and describe fully puerperal mastitis, including treatment.
2. Diagnosis and treatment of complete placenta prævia through pregnancy and labor.
3. Under what conditions may it be advisable to empty the pregnant uterus (*a*) in the interests of the child, (*b*) in the interests of the mother?
4. Give directions for obtaining measurements of the female pelvis and length of such diameters to reasonably assure successful labor at term.
5. Describe placenta and cord.
6. Discuss treatment of nonoperable carcinoma of female breast.
7. Describe any operation you may prefer for correction of retrodisplacements of uterus.
8. Causes and treatment of dysmenorrhea.
9. Indications for operative treatment in fibromyomata of uterus.
10. What is meant by Trendelenburg's position? What advantages are obtained by use of this position?

SURGERY.

1. Give the differential diagnosis of skull fracture and the signs and symptoms which call for operative interference.
2. Describe in detail the characteristic picture of a patient with perforated duodenal ulcer. Differentiate from gallstone colic.
3. Describe the complete treatment of open fracture of the mandible with displacement of the fragments.
4. Discuss deep cervical suppuration.
5. Give the diagnosis, differential diagnosis, and treatment of carcinoma of the tongue.
6. Discuss the treatment of chronic empyema.
7. Give the diagnosis, differential diagnosis, and treatment of gonorrheal monarthritis.
8. Discuss the etiology and treatment of chronic leg ulcer.
9. Describe the etiology, signs, and symptoms of acute intestinal obstruction.
10. Give the diagnosis and differential diagnosis of stone in the ureter.

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. MASTITIS. *Varieties:* Acute, chronic, puerperal, tuberculous, and syphilitic.

PUERPERAL MASTITIS. *Etiology:* Infection, generally due to handling; cracked or sore nipples and overactivity of the gland with retained secretion are predisposing causes.

Symptoms. The breast is swollen, painful, and tender, and, owing to the soreness of the nipple, the breast is not relieved of its secretion, so that it is distended. If suppuration follows, redness, edema, and fluctuation occur over the site of the abscess. The abscess may be—(1) supramammary, the pus lying between the skin and breast; (2) intramammary, or the common form, in which the pus is in the substance of the breast; (3) submammary, which is beneath the breast, and may spread from the deep lobules, but more frequently is due to disease of the underlying ribs." (*Aids to Surgery*)

Prophylactic measures consist in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple before and after nursing, and by proper attention to hygienic conditions before labor, and the nipple and breasts being preserved from pressure. *Treatment* before suppuration occurs consists in supporting the breast with a bandage, emptying the gland regularly with a breast pump, and applying a belladonna plaster over the gland to stop the secretion and allay the pain. Nursing from the affected breast should be stopped at once. When pus is present an incision should be made at once, or the abscess may burrow extensively and riddle the breast. The incision should be made in a line radiating from the nipple, so as not to cut the ducts; it should be free, and all pockets opened up with the finger. Then a large drainage tube is inserted and shortened daily, as the wound heals by granulation. If necessary, several incisions are made.

2. COMPLETE PLACENTA PRÆVIA. *Symptoms:* "Usually there are none in the early months, though the woman may bleed as early as the third month. The first warning is a sudden outpour of blood of greater or less amount. The first hemorrhage is most frequently observed in the seventh or eighth month, rarely not until the onset of labor. The bleeding is usually most profuse just as the uterine contraction passes off. It may cease altogether with the pain. Hemorrhage during pregnancy always demands immediate investigation to determine the source of bleeding. This is doubly imperative when it occurs in the later months. Placenta prævia is distinguished from accidental hemorrhage and from uterine rupture by the physical signs. Very rarely bleeding may proceed from a lesion of the venous network of the decidua vera, the situation of the placenta being normal.

Physical Signs: "(a) *Abdominal.*—The location of the placenta may sometimes be made out by abdominal palpation. Beneath the placenta the fetal parts are obscure to the touch, elsewhere they are more distinctly felt. In most instances of anterior implantation the convex edge of the placenta can be traced as a resisting ring. Abnormalities in the presentation and position of the fetus are common, owing to the occupation of the lower uterine segment by the placenta. (b) *Vaginal.*—Examination will show (1) Unusual development of the cervix, especially when the placenta prævia is complete, and pulsating vessels are detected around the cervix. (2) A cushiony mass may be detected between the presenting part of the fetus and the examining

finger. (3) There is a bogginess of the cervix, vaginal vault, and the lower uterine segment. (4) The characteristic stringy feel of the detached surface of the placenta may be noted on examination through the cervical canal; the uneven surface of the cotyledon and a gritty feel distinguish it from blood-clots, which are more friable. It should be borne in mind that the portion of placenta over the cervix may be only an adventitious cotyledon."

Treatment: "(a) *Before Viability.*—Generally the pregnancy should be terminated as soon as a positive diagnosis is made. Exceptionally, the treatment may be expectant, provided the patient is in a hospital under constant observation. Partial or complete rest must be enjoined, according to the amount of bleeding, and a general regimen prescribed very similar to that pursued for the arrest of threatened abortion or premature labor. If the hemorrhage is copious, the placenta prævia complete, or the fetus dead, the uterus should be immediately emptied. (b) *After Viability.*—Induction of labor is indicated immediately the diagnosis is made, simple cases excepted. *Management of Labor.*—The principal indications in the management of labor with placenta prævia are the control of hemorrhage and the securing of dilation of the cervix. Hemorrhage under control, urgent measures are not necessarily required, but the obstetrician should remain with the patient until she is delivered." (Polak's *Manual of Obstetrics.*)

3. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head.

4. *External pelvimetry:* "The measurements are made with a pair of calipers. *Interspinous diameter:* The points of the calipers are held in the two hands so that the point of the forefinger rests alongside the point of the instrument. The two anterior superior spines are located, and the points placed on them. The calipers are then screwed tight by an assistant or nurse, and the measurement read off. Normally it is 9½ to 10 inches. *Intercristal diameter:* The instrument is held as before and the points passed slowly around the iliac crests until the points of greatest separation are found, when the measurement is made. Normally it is 10½ to 11 inches. The *external conjugate diameter* is measured by placing the one point of the calipers over the tip of the last lumbar spine, and the other over the front of the symphysis pubis. This is most easily done with the patient standing, and the tip of the last lumbar spine can be found by counting downward from above. It is, however, usually marked by a slight dimple due to fascial attachments. In fat persons it suffices to make a point in the midline 2½ inches above the line joining the posterior superior iliac spines. The external conjugate usually measures about 7½ to 8 inches; 3½ inches at the very least must be allowed for the thickness of the bony and soft tissues. Therefore, while a large reading may not necessarily mean a large conjugate, a reading under 7½ inches, and more especially under 7 inches, indicates that the conjugate is diminished proportionately.

"*Internal pelvimetry:* The *diagonal conjugate* from the promontory of the sacrum to the under margin of the symphysis may be measured by the fingers. The diagonal conjugate measures 4½ to 4¾ inches, and ½ to ¾ of an inch must be subtracted to give the length of the conjugate vera. The actual amount to be subtracted varies with the depth of the pubic bone and its inclination toward the sacrum, so that at the best this method of estimation is but approximately correct. In practice, however, these methods are found to be sufficiently accurate in the vast majority of cases. It should be remembered that in a normal pelvis it is impossible to touch the promontory of the sacrum by vaginal examination without forcing the fingers so far in as to hurt the patient. Therefore, if the promontory can be felt readily, it indicates a small pelvis and the desirability of more careful investigation. The *outlet of the pelvis* can be directly measured in both its anteroposterior and transverse diameters by means of the fingers and a measuring tape, or more conveniently by means of a pair of calipers with the points crossed."—(Johnstone's *Textbook of Midwifery.*)

5. At full term the *placenta* is a soft, spongy mass, roughly saucer-shaped, from 6 to 9 inches in diameter, about ¾ of an inch in thickness at the central point, and weighs about one pound. It is *formed* partly from the mucous membrane of the uterus and partly from the chorionic villi. Its *usual location* is on the anterior or posterior wall of the uterus, near the fundus.

The *umbilical cord.*—"At term the cord has been compared to a 'twisted rope of tissues,' extending from the placenta to the child. The cord is of a glistening grayish-white color, of varying thickness, and is usually about 22 inches long, but may be either much longer or shorter. In structure the cord consists of a covering of epithelium continuous with that of the amnion, which surrounds a jelly-like matrix called Wharton's jelly. This consists of mucin, branched corpuscles, and embryonic connective-tissue cells. Within this substance the two arteries and one vein run in a spiral course, usually from left to right; it is to the fact that the growth in length of the vessels exceeds that of the rest of the cord that the twisted appearance of the latter is probably due."—(Jewett's *Practice of Obstetrics.*)

6. *Treatment of inoperable carcinoma of the female breast.* Oophorectomy has been recommended for recurrent cases in women before the menopause. Large doses of thyroid extract, injections of trypsin, Coley's fluid for sarcoma, and *x*-ray treatment have all been recommended. The *x*-ray treatment is said to diminish the pain and prolong life.

7. *Alexander's operation:* "The pubic hair is shaved off and skin and vagina disinfected. The uterus is replaced and a glass stem with attached silk thread introduced into its cavity. A narrow Hodge pessary is placed in the vagina. Next, the patient's legs are extended. The operator stands on the side opposite to the ligament to be shortened; he locates the pubic spine, which is the leading landmark during the whole operation, and makes an incision from 1 to 3 inches in length through the skin over it, in the direction of the slit between the pillars of the external inguinal ring. Its length must be proportionate to the amount of adipose tissue present, but it should, if possible, not extend beyond the hairy portion of the mons Veneris, as then, after the hairs grow out again, the cicatrices will be entirely hidden. Next, the subcutaneous fat and the superficial fascia are divided in the same direction, exposing the glittering, satin-like pillars of the external ring, which is situated above and a little outward of the spine of the pubis and can be felt at the bottom of the wound. It is well to dissect the aponeurosis of the external oblique abdominis muscle, so as to see not only the pillars, but the intercolumnar fascia extending between them. During the incision several small arteries will be severed and must be clamped. In the external inguinal ring is seen a lump of fat which contains the ligament. This whole mass is grasped with an artery-forceps and drawn in the direction of the vulva. The genital branch of the lumbocrural nerve is seen as a fine white cord in front or to one side of the ligament. If it is in the way, it may be cut, but generally it suffices to push it aside. From the ligament extend a number of sinewy threads to the sides of the inguinal canal, which must be severed. Sometimes the peritoneum is invaginated and forms around the ligament a sheath, which must be stripped back with the nails of the fingers. When the isolated white tendinous ligament peels readily out from the canal, the wound is covered with iodoform gauze or sterile gauze; the operator takes his position on the other side and treats the second ligament in the same way. Before fastening the ligaments he should pull both forward and ascertain through the abdominal wall or the vagina, that the uterus is tilted forward. He should then slacken them from ¼ to ½ inch, in order to avoid undue strain on them and the formation of a hernia. They are fastened by passing three sutures of chromicized catgut through them and both pillars on each side, the last one comprising some of the tendinous tissue in front of the pubic bone. When the sutures have been tied, the superfluous piece of the ligament, which will measure from 2 to 4 inches, is cut off. The superficial fascia is closed with running suture of plain catgut and finally the skin wound is closed with two or three sutures of silkworm gut. The two wounds are dressed with one piece of iodoform gauze, guttapercha tissue, and plain

gauze, kept in place by a double spica or straps of rubber adhesive plaster. At the end of a week the superficial sutures are removed. The patient should remain in bed three weeks."—(Garrigues' *Gynecology.*)

8. DYSMENORRHEA. *Causes:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis, or obstruction of the cervix, prolapse, or displacement of the uterus. *Treatment:* If possible remove cause; attend to the general condition, hygiene, tonics, regular habits, etc.; curettage may be necessary, and may have to be repeated (perhaps more than once).

9. *Operative treatment in cases of fibromyomata of the uterus* is always indicated unless there are also present serious complications which render the operation either impossible or extra hazardous. Extreme age, weakness, and incompetent cardiac action are often classed as contra-indications.

10. *Trendelenburg's position* is one in which the patient is placed with the pelvis raised and the head and shoulders lowered.

Its *advantages* are:—The intestines fall towards the diaphragm and the pelvic cavity is exposed to view. This is effected by gravity and so the intestines are saved from the bruising and irritation which would be caused by undue handling. Further, the operator has more room, and a clear field of vision for the operation. Hemorrhage can be more quickly controlled because its source is more likely to be visible. Shock is said to be lessened.

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.	DIABETIC COMA.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma, sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.	Deep coma. Sweetish odor to breath.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated	Pupils contracted to pinpoint size	
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.	
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration	Respiration very slow—may be 6 to 8 per minute.	
Temperature higher —101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.		
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal	Normal.	Urine contains a variable amount of sugar and diacetic acid.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.				

SURGERY.

1. In *fractures of the base of the skull* there will be:—Hemorrhage (from nose, into orbit, from ear, or into tissues), escape of cerebrospinal fluid from nose or ear; concussion or laceration of brain, with coma; various nerve lesions (blindness, ocular paralysis, facial paralysis, deafness).

In fractures of the vault of the skull: If there is a wound, the fracture and depression may be seen, and blood, cerebrospinal fluid, or brain, may be escaping. If there is no wound a careful examination is necessary, as a hematoma may form and obscure the depression. In cases of doubt an incision should be made.

In a *simple depressed fracture* there is usually some concussion, which is followed by compression from hemorrhage in the neighborhood. The depressed bone also causes compression later by the *spreading edema* it sets up in the brain. Death may result quickly, or the patient may recover and then become the subject of traumatic epilepsy from irritation of the cortex. If the depression is over the motor area convulsions or paralysis are quickly induced.

In a *compound depressed fracture* the blood escapes and does not produce compression. Concussion may or may not be present. The advent of sepsis produces inflammation of the bone, membranes, and brain, which may be limited if the drainage is free; but if not death soon follows from compression by the inflammatory exudation. During the stage of compression a hernia cerebri is formed. If the depressed fragments are early removed and asepsis is maintained the patient has a good chance, unless the brain itself is severely injured. —(From *Aids to Surgery.*)

The following table (from Eisendrath's *Surgical Diagnosis*) gives the differential diagnosis:

"The indications for operation may be epitomized thus:

(i.) In all punctured fractures, operate.

(ii.) In all compound depressed fractures, operate.

(iii.) In simple depressed fractures: In adults, always operate; in children, if gutter-shaped, operate; if pond-shaped, wait for symptoms, unless the fracture is a bad one."—(Rose and Carless' *Manual of Surgery.*)

2. In *duodenal ulcer,* the patient complains of pain of a dull aching character, felt to the right of the midline, and coming on about three or four hours after meals; vomiting; blood may be passed with the feces, or hematemesis may occur. It is most frequently located in the first part of the duodenum, being that part which is acted on by the acid chyme from the stomach.

When perforation occurs, there is sudden and severe abdominal pain, vomiting, rapid pulse and shock. The abdomen becomes rigid and tender, the temperature becomes subnormal, and later rises, and the symptoms of peritonitis develop.

In *gallstone colic* the pain is paroxysmal, radiates to the right shoulder; the pain does not occur regularly every day and at a fixed time after meals; the gastric content should be normal; jaundice may be present.

3. "*The Treatment of a fractured mandible* is frequently a troublesome matter, owing partly to the septic element, and partly to the difficulty of fixing the jaw without interfering with the patient's nutrition; hence the co-operation of a skilled dentist should always be secured. Teeth loosened by the injury will probably require removal, and at the same time it is wise to extract septic teeth or roots, so as to be able to keep the mouth in a more cleanly condition. (1) As a temporary measure, and indeed as a permanent appliance in simple cases without much displacement of the fragments and where dental assistance is not at hand, all that is needed is an efficient four-tailed bandage. . . . The bandage is maintained firmly in position for three weeks, the patient being fed through a tube passed between the teeth or through the gap behind the last molar, and all movement of the jaw prohibited. The mouth should be frequently washed out with some antiseptic lotion. Union is usually secured in five weeks. (2) If patients are unruly, or if the above method fails to maintain the fragments in position, a moulded paroplastic or leather splint may be applied. It is lined with lint, and secured by bandages or tapes passed

through holes. (3) Where there is much displacement, the fragments must be fixed. Wire sutures passed around or between adjacent teeth and tied are distinctly objectionable, causing the teeth to become loose and perhaps diseased. *Hammond's wire splint* is the best apparatus to employ. It consists of a firm wire collar or framework, which encircles the whole series of teeth in the lower jaw. It is accurately fitted by a dentist, firstly, to a cast of the jaw, subsequently to the jaw itself, and is fixed by several wires passing from one half to the other between the teeth. (4) In cases where a Hammond's splint fails in remedying the displacement, or where the teeth are defective, a Kingsley apparatus may be used with advantage. It consists of a vulcanite splint fitted over the teeth or alveolar process of the mandible, and extending for a sufficient distance on each side of the fracture to steady the fragments. To the front of this are attached curved metal bars, which extend sideways from the angles of the mouth over the cheeks. It is kept in position by passing a bandage over the bars and under the chin. (5) Wiring of the fragments together may be required in a few cases. The wires must be passed either through the bone or below the teeth, or through the empty alveoli of neighboring teeth which are extracted for the purpose. When septic inflammation occurs of such severity as to lead to necrosis, it is best to delay all operative treatment until the sequestrum has been detached, and the parts are more healthy, the patient's mouth in the meantime being frequently cleansed with antiseptic lotions. Wiring of the fragments may then, if necessary, be undertaken with good hope of success."—(From Rose and Carless' *Manual of Surgery.*)

4. "*Cellulitis of the Neck* is usually secondary to a septic throat, and therefore associated with follicular tonsillitis, diphtheria or scarlatina, the process probably starting in a deep lymphatic gland; it occasionally follows operations on the neck. The tissues beneath the deep cervical fascia become infected, usually with streptococci, and sooner or later suppuration occurs. The affected side of the neck is swollen, red and brawny; severe pain of a deep tensive character is experienced, and this is increased by movements of the head or jaw. The swelling is often peculiarly hard and resistant and although edema may be present, it may be several days before the surgeon can detect any focus of softening suggestive of suppuration. During this period the constitutional symptoms are severe; fever may be high, and the pain and subsequent sleeplessness may exhaust the patient, whilst the difficulty of swallowing hinders his nutrition. Dangerous symptoms arise from pressure on important vessels and nerves, from extension of the inflammation to the mediastinum or to the glottis, causing edema and consequent dyspnea, or from the supervention of pyemia owing to venous thrombosis. The process usually ends in sloughing of the cellular tissue and suppuration, the pus burrowing widely if a free exit by incisions through the deep fascia is not provided."—(Rose and Carless' *Manual of Surgery.*)

5. CARCINOMA OF THE TONGUE. "The clinical appearances vary widely. Sometimes the surface presents a warty growth; sometimes it is excavated, forming a deep ulcer with raised nodular edges; in other cases the ulcer is smooth, and its edges even and rounded. Extreme hardness of the edges and base of the ulcer is always a characteristic feature. The tongue tends to become fixed, especially when the disease spreads to the floor of the mouth, so that it cannot be protruded, and the restriction of its movement produces a characteristic interference with articulation, certain words being slurred, and when the fixation is extreme it may interfere with mastication and swallowing. The patient complains of a constant gnawing pain in the tongue, and of severe pain shooting along the branches of the fifth nerve, and especially towards the ear. In the advanced stages there is salivation and fetor of the breath. When the disease is situated on the edge of the tongue it tends to spread to the floor of the mouth and to invade the lower jaw. If situated far back on the dorsum, it spreads on to the epiglottis, the pillars of the fauces, and the tonsil. The neighboring lymphatic glands—particularly those under the jaw and along the line of the carotid vessels—soon become enlarged, so that they are palpable. The submaxillary and sublingual salivary glands may also be affected.

Differential Diagnosis.—"Cancer of the tongue has to be diagnosed from syphilitic and tuberculous affections, from papillomata, and from simple ulcers and fissures. It is to be borne in mind that any of these conditions may take on malignant characters and develop into epithelioma. The microscopic examination of a portion of the growth removed under local anesthesia is often the only certain means of establishing the diagnosis, and should be had recourse to as early as possible. When there is still doubt as to the nature of the growth, it should be treated as if it were cancerous. *Gummatous ulcers* are usually situated on the dorsum of the tongue, are frequently multiple, and have sloughy, undermined edges; the surrounding parts, although indurated, are not so densely hard as in cancer; there is not necessarily any involvement of lymphatic glands. The cancerous ulcer is usually single and situated on the edge of the tongue; its edges are hard, raised, and nodular; and the glands are usually enlarged and hard. Little reliance is to be placed on the therapeutic effects of anti-syphilitic drugs in the differential diagnosis, as they are often inconclusive, and result in loss of time. *Tuberculous ulcers* usually occur in association with other unmistakable evidences of tuberculosis. *Papillomata*, when sessile, may simulate cancer; they show a marked tendency to become malignant. *Simple ulcers and fissures* are usually recognized by the history of the condition, the absence of induration and of glandular involvement, and by the fact that they heal quickly on removal of the cause.

Treatment.—"The only treatment that offers any hope of cure is free removal of the disease, and experience has proved that unless this is done early the prospect of the cure being a radical one is remote. Not only must the segment of the tongue on which the growth is situated be widely excised, but all the lymphatic connections must also be removed whether the glands are palpable enlarged or not."—(From Thomson and Miles' *Manual of Surgery.*)

6. "*The treatment of chronic empyema* consists in removing a sufficient amount of the chest wall to enable the parietes to fall in and lead to the obliteration of the cavity—*thoracoplasty.* This may be done by the Estländer-Schede operation, which consists in excising subperiosteally portions of several ribs, the number and length of the portions resected depending on the size and shape of the cavity to be obliterated. One or more incisions are made over the ribs to be dealt with, or a large horseshoe-shaped musculo-cutaneous flap, extending from the fourth to the ninth or tenth rib, is turned up, and the exposed ribs resected. The periosteum, the intercostal muscles, and the thickened parietal pleura are then removed, and the cavity packed with gauze before the flap is replaced. When the lung is firmly bound down in the vertebral groove, multiple incisions may be made through the thickened visceral pleura, or the procedure known as 'decortication of the lung' may be carried out as an addition to thoracoplasty. This consists in peeling off the thickened pleura from the surface of the lung, and stitching the latter to the skin flap."—(Thomson and Miles' *Manual of Surgery.*)

7. GONORRHEAL MONARTHRITIS.—"The disease may begin suddenly with severe pain, swelling, tenderness, redness, and edema of the affected joint. The general symptoms in such cases are extreme. There is but little fluid in the joint, the swelling and pain being the most marked local signs. In a few cases intraarticular abscesses form at an early period. After such an acute onset, the course of the case becomes very chronic, resulting in complete destruction of the joint, *i.e.*, its ligaments become lax, the cartilages are destroyed, and ankylosis follows. Gonorrheal arthritis may run a subacute or chronic course from the onset. The patients often complain of flying pains in the joints. There is no swelling, but loss of function and ankylosis frequently follow. The majority of cases of gonorrheal arthritis appear during the latter weeks of the acute stage of the disease. The condition also appears in the subacute or chronic cases.

"There is usually no difficulty in making a diagnosis, even without a bacteriological examination. The first step is to examine the urethra for pus, and the urine for clap shreds, and then stain these for the gonococcus. The only form of acute arthritis which requires differentiation, is articular rheumatism. Both of these may

begin as polyarticular lesions. Acute rheumatism is more apt to involve the smaller joints of the fingers or toes than is the gonorrheal form. In many cases the local signs are so similar in their severity as to make a differentiation impossible. The presence of a local gonorrheal infection should be sought for. If the gonococcus is found in the joint exudate, the diagnosis is confirmed. This latter is unfortunately technically a very difficult mode of diagnosis, and often results negatively. Gonorrheal arthritis is more frequently monarticular than is the ordinary acute form; there is also an absence of cardiac or other serous complications in the gonorrheal form, and a greater tendency to early ankylosis. In the more chronic forms of gonorrheal arthritis without much effusion and no tendency to ankylosis, the differentiation from chronic rheumatoid arthritis is very difficult. The most important point is to find the primary focus in the genito-urinary tract."—(Eisendrath's *Surgical Diagnosis.*)

"The *treatment* is unsatisfactory, the disease being apt to persist or recur. The urethritis should be combated, and the joints immobilized and treated locally as in other forms of arthritis. As soon as the pain subsides, passive motions should be employed to prevent ankylosis. Among the internal remedies which have been used are the salicylates, iron, quinine, strychnine, and the iodides. If suppuration occurs, the joint should be opened, irrigated, and drained. Rogers and Torrey claim good results from the hypodermic injection of an antigonococcus serum, prepared by injecting cultures of the gonococcus into rabbits. From twenty to sixty minims are administered every day or every other day until the pain and disability subside. Vaccines made from the gonococcus also have been employed."—(Stewart's *Manual of Surgery.*)

8. "CAUSES OF CHRONICITY OF ULCERS.—(1) *Defective circulation:* In lower parts of legs; in those who stand all day; in old people. (2) *Venous obstruction:* Varicose veins; after venous thrombosis, *e.g.*, "white leg;" pregnancy. (3) *Fixation of the ulcer to the underlying bone or fascia:* Prevents the edges being drawn together; prevents the base being drawn up to the edges; prevents the proper vascularization of the base of the ulcer necessary for the formation of granulations. (4) *Constitutional conditions:* Bright's disease, gout, diabetes. (5) *Continued irritation:* When an ulcer is left dirty and without any dressing. (6) *Pressure of edema.* This causes the vessels in the neighborhood to be occluded, and produces an extension of the ulcer."

"TREATMENT OF CHRONIC SIMPLE ULCERS.—(1) *Posture:* Rest with elevation of the foot. (2) *Pressure:* Simple or elastic bandages; starch bandages over dressings; strapping. (3) *Unna's Paste* is the most useful routine treatment because it combines uniform pressure with the application of a stimulating medicament. In the case of large foul ulcers a window may be cut in the dressings over the sore and the ulcer dressed daily. It is changed once a week. (4) *Dressings:* When the surface is foul: Charcoal or boracic fomentations. For mere indolence: Metal, *e.g.*, a piece of pewter cut to the size and shape of the ulcer; metallic ointments, especially zinc; resins, *e.g.*, resin ointment; oxygen, applied for half hour daily. Method: If the ointments are used they should be spread on lint cut to the shape but rather smaller than the ulcer. All old ointment should be cleaned off daily with oil. (5) *Operative treatment:* Multiple incisions in a longitudinal direction to relieve congestive edema. Undercutting the ulcer edges so as to free them from deep adhesions. Tying prominent varicose veins above the ulcer. Skin grafting: Most useful in traumatic, *e.g.*, burn ulcers. Amputation: For old ulcers of large size with base fixed to the periosteum. For ulcers encircling more than half the circumference of the limb and producing great edema of the parts below. For epithelioma."—(Grove's *Synopsis of Surgery.*)

9. ACUTE INTESTINAL OBSTRUCTION.—*Etiology:* "(1) Strangulation by bands or adhesions or through apertures; (2) volvulus; (3) acute intussusception; (4) the termination of chronic obstruction; (5) the impaction of foreign bodies; (6) strangulation over a band, or acute kinking (rare). These are mechanical causes; another common cause is peritonitis, which is an inflammatory cause.

Symptoms: "Sudden severe pain referred to the umbilicus comes on, perhaps, after an effort. Shock, evidenced by a weak pulse, a cold, clammy skin, and a subnormal temperature, accompanies the pain. The pain, intermittent at first, becomes continuous. Vomiting is persistent, and soon becomes fecal-smelling. The patient becomes exhausted by the vomiting and inability to take food. The abdomen becomes distended, and if the obstruction is not relieved, perforative peritonitis follows, so that the patient dies in about seven to ten days from the onset. Constipation is usually absolute, though the lower bowel may empty itself at first."—(*Aids to Surgery.*)

10. STONE IN THE URETER.—The symptoms are: Colic. Pain shooting along ureter. Tenderness over ureter. Hematuria. Anuria (if opposite kidney is blocked or diseased). Abdominal tumor (persistent or intermittent). Urine contains crystals, blood, or pus. Prolapse of ureter into bladder. Skiagram shows stone. In the majority of cases the symptoms are simply those of renal calculus, and diagnosis is only complete on lumbar exploration and passing ureteral sound. In some cases the stone can be felt per rectum or vaginam.

"*Differential diagnosis.*—(1) *From encysted vesical calculus:* Impossible clinically. (2) *From cystitis:* In this: Urine is alkaline. Pus at beginning or end of micturition. (3) *From ureteritis:* Difficult in absence of history of colic. (4) *From vesical tuberculosis:* In this: Tubercle in urine. Polyuria. Frequent micturition. Slight hematuria. Symptoms not relieved by rest. (5) *From prolapsed inflamed ovary:* Ovary lies behind broad ligament and at greater distance from vaginal wall. Stone is felt in antero-lateral fornix. Hardness and outline are more definite.

"*The skiagram* shows a shadow in the course of the ureter, but this has to be distinguished from that of calcareous iliac glands or that of an appendix concretion (the latter very rarely throws a shadow). *Ureteral catheterization* through the cystoscope not only shows which side is affected, but the end of the catheter may touch the stone and a waxed tip receives a scratched impression."—(Groves' *Synopsis of Surgery*).

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

OPERATIVE SURGERY. By JOHN J. MCGRATH, M.D. 863 pages, with 369 illustrations. Price, $8.00. Published by F. A. Davis Company, Philadelphia.

CHIRURGIE DER WIRBELSÄULE, DES RÜCKENMARKS, DER BAUCHDECKEN UND DES BECKENS. Von Dr. G. LEDERHOSE. 160 pages, with 20 illustrations. Published by Georg Thieme, Leipzig.

KRANKHEITEN DES GEHIRNS UND DES VERLAGERTEN MARKS. Von Prof. Dr. E. MEYER. 128 pages, with 15 illustrations. Published by Georg Thieme, Leipzig.

URINARY ANALYSIS AND DIAGNOSIS. By LOUIS HEITZMAN, M.D. 362 pages with 131 illustrations. Price, $4.00. Published by William Wood & Company, New York.

CANCER AND ITS NON-SURGICAL TREATMENT. By L. DUNCAN BULKLEY, M.D. 457 pages. Price, $6.00. Published by William Wood & Company, New York.

THE GENUINE WORKS OF HIPPOCRATES. By FRANCIS ADAMS, M.D. 754 pages. Price, $5.00. Published by William Wood & Company.

CLINICAL BACTERIOLOGY AND HÆMATOLOGY FOR PRACTITIONERS. By W. D'ESTE EMERY, M.D. 310 pages with illustrations. Price, $3.50. Published by P. Blakiston's Son & Company, Philadelphia.

SQUINT. By CLAUD WORTH, M.D. 242 pages with illustrations. Price, $3.50. Published by P. Blakiston's Son & Company, Philadelphia.

THÉRAPEUTIQUE CLINIQUE. Edited by A. MARTINET and a Staff of Collaborators. Volumes one and two. 1340 pages with illustrations. Published by Masson & Cie., Paris.

Miscellany.

THIRTEEN.

A STATISTICAL REPORT OF THE CLASS OF 1881 OF HOBART COLLEGE.

By BRANDRETH SYMONDS, M.A., M.D., LL.D.,

NEW YORK.

As a matter of vital statistics, the number thirteen has great significance for us on account of the old superstition attached to it. This says that if thirteen persons partake of a meal together, one of them will die during the ensuing year. It is essential that these persons actually partake of the meal. The presence of an extra person or two as servitors does not count. No dinner party of twelve suffers the slightest compunction, though oftentimes only one servant will be present in the room. It seems necessary also that the meal should be eaten with a common interest or in a community manner. In a restaurant, for example, the presence of one extra diner seated at a table near by, but not belonging to a party of twelve, would not be considered to raise it to thirteen. A party of thirteen seated in a restaurant falls under the ban even though there are many other diners in the same room. Furthermore, for the time being the thirteen diners are on a social equality, whatever may be their levels before and after. Much stress is laid upon this point. The clerk or the governess who is brought in to raise the fatal thirteen to an innocuous fourteen is always treated as a social equal, perhaps even disguised for the purpose, and no guest outside the family is ever requested to stay away in order to bring the number down to twelve.

Thirteen is certainly a definite element in the superstition, but did it always refer to the number of banqueters? Is it possible that it was attached to another factor at one time? The origin of the superstition lies far back, long before history. It certainly antedates the Last Supper of Our Lord, for this was followed by the death of two, though one came to life again on the third day. As no variant of the superstition has ever suggested this possibility, this origin can be dismissed. Many a bit of ancient folklore has received a similar Christian gloss.

It seems likely that this dates almost from the earliest Aryan calendar. As long as they were huntsmen only, our ancestors' very first calendar doubtless comprised only the month, the usual lunation of 29d. 12h. 44m. 7.2s. This is very nearly 29½ days, and in order to keep the record straight they alternated months of 29 and 30 days. It was necessary to know beforehand, for hunting, the nights of the bright moon and of the dark moon. When they became shepherds and herders, a solar calendar was needed as well as the lunar, and this need was emphasized when they took up farming, even in its most primitive form. The first solar calendar comprised a year of 12 months, of 29 and 30 days alternately, which makes 354 days. This is more than 11 days short of the real solar year of 365¼ days. So they intercalated 12 days at the end of the regular year, in order to start the new year at the proper point.

Our ancestors stood at this time, in point of culture, only little above the North American Indians when Columbus discovered this country. They were inferior to the Aztecs and Incas in all items of civilization, and as cruel as the former. Among such primitive people the earth, the air, and the water and everything upon them, under them, and within them are populated with demons whose function is to harass and destroy human beings and their dependents. These demons have greater license and are more malignant on intercalary days, for such days are out of the regular order and do not belong to the customary ritual. On such days mock chiefs and kings were selected who substituted for the proper authorities, doubtless with their consent and perhaps at their demand. For if a particularly dire demon got loose at this time, he would seize the substitute chief in full thought that he was getting the real authority. Indications of this idea have persisted even into the last century, in the shape of such fossils as the King of Misrule, the Abbot of Unreason, the Boy Bishop and Archbishop, and the Lord of Twelfth Night. Substitution pervaded even the family in these intercalary days, and the slave and the serf sat at table with the master and mistress and ate their meals in common with them. Perhaps the master and mistress waited on them, for all social distinctions were abolished and everyone was on a social equality. As prohibition was unknown and alcohol was just as potent in driving away the blue devils then as now, everybody got joyously drunk without a thought of morals or posterity. For twelve days the mad, drunken revelry went on with all authority topsy-turvy. But the thirteenth was the day of reckoning when the regular order was reestablished. The real chiefs and kings again took command, and then what became of the substitute chiefs and kings? They went to the high places and there, at the altars of Saturn or Chronos or some other cruel and bloodthirsty deity, they were sacrificed without remorse or pity, just like the Aztecs. Perhaps they were sacrificed as scapegoats, so that the tribe could start off the new year with the old sins wiped out. Perhaps they were sacrificed as gods of vegetation and fertility, who were killed in the full flush of health and vigor in order that the crops might be abundant. Whatever the motive, for them the thirteenth day was fatal and doubtless the regular authorities were glad to get rid of them. It was the thirteenth day then and not the thirteenth person which the faint, flickering memory of that ancient time recalls in our present superstition. There are many fossils in folklore of the twelve intercalary days. Frazer in his "Golden Bough" cites many hundreds of them. Our little superstition is the only reminder left of the fatal thirteenth day on which one human being died, who had been for twelve days the social equal of the chiefs of the tribe and had eaten and drunk with them as their peer.

How far afield statistics will lead a man who loves fairy stories. So let us get down to the brass tacks of our own class of '81.

In June, 1877, just one man received a baccalaureate degree at Hobart. In September, 1877, five of us started the class of 1881, and we adopted

as our class motto "Vires acquirit eundo," which every pundit says signifies that the class would gain strength by going on. But let me draw your attention to the fact that vires is plural and means forces as well as strength. So we lived up to our motto and gained five more members in our freshman year. We lost two at the end of it, but gained six during our sophomore year, though we lost two at the end of that. We lost one more at the end of our junior year, but gained two in the senior year. So we finished with thirteen, and that number sat down together at our senior class dinner. Before our time this number was guaranteed to raise our mortality out of sight within one year, for one actual death would have been nearly twenty times the number of deaths expected among thirteen men at our average age—22 years and 4 months. This would be a mortality ratio of nearly 2000 per cent, something awful to think of, even though it means only one death.

We went on our way rejoicing, in spite of this demon, who has now been exorcised by our precept and our example. In the 40 years that have elapsed since then, 6.8—more than one-half of us—ought to have died, but all 13 are still alive and kicking. Some of us have been very near the edge of the valley, but all have come back, just to show what '81 and Hobart can achieve.

Looking at the other end of life, our dates of birth range from July 6, 1853, to March 4, 1863, a span of ten years. The oldest is now nearly 68 and the youngest just over 58. Ten of us went into orders very early. One of these dropped out a few years ago, and just about that time another one went in, so that ten of us are still clergymen. The others went into the law and medicine.

Each one of us has done his best by his country, but when it entered the Great War, four years ago, the youngest was 54 and he had a rotten heart. So none of us got into active service, though we all worked hard in the thousandfold duties which developed at home. Those of us who had sons and daughters old enough lent them to our country, and they all returned, save that MacLure lost his daughter's husband, who had made a splendid record in France and then came back home to die of influenza in camp.

We have averaged over two children apiece and some of us have grandchildren. May their record for longevity be as good as ours. To insure this they should first drink deep of the Pierian spring at the foot of Seneca Lake. Then they can say with proper pride, "We, too, belong to the class of 1881 at Hobart."

1 West Ninety-fourth Street.

The New University of Cluj, Roumania.—A descriptive article in *La Presse Médcale*, 1921, xxix, 15, states that the doors of this new school have been open to students for about a year. A corps of young professors has been assembled from the older universities of the kingdom, and it is the intention to complete the faculty with French professors and make the new institution preeminently Latin in culture. The incumbents in the chairs of the various sciences have mostly French names. The university town of Cluj already shelters about 2000 students who come from Transylvania and elsewhere. A Pasteur Institute for general research will soon be established. The installation for clinical instruction and laboratory work will be superior in character. Each clinic will have its separate amphitheatre, operating room, laboratory, etc. The older universities at Bucharest and Jassy have naturally been drawn upon heavily for good men, and many of these have been assistants to the famous medical Roumanians, Jonnesco, Marinesco, and Babès. Many of the eminent men of the older faculties received their education in the University of Paris, and the selection of prominent Parisians to fill chairs in this new school will be in obedience to tradition. Before the war there were numerous men on the university faculties who were unfamiliar with the Roumanian language and who were strongly tinctured with Teutonic ideas. Many were from Austrian or rather Hungarian colleges. The character of the textbooks will eventually be changed from German to French, if the French professor can bring it about, although German books are now much cheaper and many of the students are ignorant of the French tongue.

Prescribing for a Sick Stream.—An intensive study of stream pollution, with special regard to the establishment of a general plan by which any polluted stream in the United States might be purified at a minimum expense, has recently been begun by the United States Public Health Service. As is well known, a polluted stream tends to purify itself, but its power in this direction depends on the amount and character of the original pollution, on the volume and speed of the current, and on the extent to which new pollution is added along its course.

The Service has selected for study the Chicago Main Drainage Channel and the Illinois River (which empties into the Mississippi), chiefly because all the primary pollution of this stream originates in Chicago and is accurately ascertainable, both as to amount and character. Analyses taken along the course of the canal and river will determine the degree and nature of the changes that take place in it. Where new pollution is added, its amount and character must be ascertained; and its effect on the old pollution learned. This last is important, for it is quite possible that sundry industrial wastes might neutralize each other or might destroy certain types of organic pollution. Similar work was done on the Ohio River from 1914 to 1917; and the present study is to check the results obtained there.

The final object is to establish fundamental quantitative relationships between bacteriological and chemical pollution of a stream, on the one hand, and basic principles, such as population, industrial wastes, stream flow, and prevailing temperature, on the other. These relationships, once established, will guide the sanitary engineers as "stream doctors" in prescribing for a sick stream the sort of tonic required to restore it to health, and thereby make it available for human consumption or industrial purposes or both, as may be desired. The work in Illinois is in immediate charge of J. K. Hoskins, associate sanitary engineer of the United States Public Health Service, and is under the general supervision of Surgeon W. H. Frost.

ENCEPHALITIS COMPLETA.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

BY J. VICTOR HABERMAN, A.B., M.D., M.S.D. (Berlin)

NEW YORK.

"ONLY rarely can the diagnosis 'Encephalitis acuta' be made with certainty" (Oppenheim).

The following study comprises a brief yet complete examination of the subject of encephalitis—encephalitis in the fuller all-types-embracing sense. The matter scanned from this larger premise has peculiar interest in bringing into survey the sporadic incidence of encephalitis and its relation to various disease forms, as well as its epidemic manifestation, the latter so decidedly limelighted in the literature of the moment. There are, furthermore, the end results to be thought of which through deformities lead to orthopedics—the acute cerebral palsies of childhood—and through epilepsy and feeblemindedness to neurology and psychiatry. Finally there are the chronic forms, some evanescing out of the acute attacks, some insidious processes from the start, linking up the subject with the scleroses, with strange brain edemas and obscure lenticular disease.

1. SECONDARY ENCEPHALITIS.*

Encephalitis is an inflammation of the brain tissue (brain stem [and spinal cord]—rarely the cerebelum—being sometimes likewise involved) occurring for the most part in circumscribed areas, one or more, or in disseminated patches, less often involving a lobe, still more rarely a hemisphere or the entire cortex. It may affect the gray matter only (poliencephalitis) or—more usually—both gray and white matter diffusely (in which case we simply speak of *encephalitis*). Here no sharp clinical differentiation can be made. Strange to say, the motor area (in bulbar and pontine involvements the motor nuclei) is chiefly affected. In this secondary form a convexity involvement prevails, mostly of one hemisphere (sometimes of adjoining portions of both), tending thus far more often to hemiplegia than to diplegia. This inflammation scarcely ever leads to suppuration (it is lymphocytic, not polynuclear). In fact, when we speak of *encephalitis* we have in mind an acute, hemorrhagic, non-suppurative disease. In the exceptional cases pus forms and we have either *purulent encephalitis* or *brain abscess*.

This inflammatory process may be primary, as we shall see; usually, however—if we for the moment exclude Heine-Medin disease and the "epidemic" form—it is secondary either to the infectious diseases (bacteria or toxins of same), to intestinal, ptomaine, and occasionally gas and other poisoning, or to trauma.† Occasionally it occurs on the outskirts of an area of hemorrhage (from one cause or another), possibly, too, in the case of softening from thrombus. In the infections not only the disease toxins but the actual organisms may get into the brain.

Of the infections, those mostly implicated are influenza (to be discussed in detail below), scarlet fever,‡ measles, diphtheria,‡ pneumonia and pertussis. Oppenheim[1] cites cases following tonsillitis, and several pointing to erysipelas, Gowers,[2] a case following mumps.§ It has been seen in dysentery (Lenhartz) and in the wake of typhoid,[3] in con-

*In the present paper *Secondary Encephalitis* will be especially dealt with, though the entire field—Encephalitis Completa—is noted in the background and considered in differential diagnosis. In the subsequent paper the first form of *Primary Encephalitis*, namely Epidemic Encephalitis will be taken up.

†Such cases in which the brain tissue may be torn or bits of bone driven in without bacteria entering the brain. Occasionally through a blow or concussion without skull injury or tearing of brain substance, an inflammatory process takes place just under the external seat of injury. In brain trauma bacterial inflammation, however, has occurred even without external wounds or injury to the skull. Whether this is due to the injured brain becoming a good soil for the multiplication of stray bacteria which happen at the moment to be there—ordinarily harmless—or in some other way, we do not yet know. The encephalitis usually follows ½ to 9 days after the trauma (Ziehen). *cf.* also on trauma under differential diagnosis.

‡In scarlet fever, meningitis and encephalitis symptoms are by no means rare—yet in autopsied cases, if ear disease has not been present, little is found to explain matters. One helps oneself out of the embarrassment by then diagnosing "pseudo-meningitis" or "meningism." Encephalitis is very uncommon. When it occurs, it is cortical. Besides the usual encephalitis symptoms one has occasionally noted an impulsion symptom—the tendency constantly to turn in one direction (Romberg in No. 11, p. 145). Occasionally, just before or after the fall of temperature, a confusional psychosis may for a brief time obtain. There may also occur in scarlet fever a hemiplegia due to embolism (autopsied case by Chapelle and Taylor) and finally a pyemic-metastatic involvement of the brain (just as there may be a joint or kidney involvement). In an extremely interesting case of Bungart's (for details and reference see under "Differential Diagnosis") the patient, an adult, because of continuing convulsions, was trephined. An area of encephalitic softening was found in the left temporal lobe, and drained. *He recovered entirely.* A case of scarlatinal encephalitis of the cerebellum was demonstrated at the Society of N. & P. in Vienna, in June 1919.

§A study of A. L. Dynkin's makes it appear that cases heretofore possibly taken for encephalitis are really due to embolism following cardiac involvement (thrombosis of the cerebral vessels). Dynkin does not

nection with malaria, and once with erythema nodosum. The tubercle bacillus may provoke encephalitis (Nonne) and also the Weichselbaum diplococcus, the latter even without involving the meninges. Recently anthrax, unsuspected, was discovered as the cause in a group of cases. In a patient of Königsberger gonorrhea appears to have been the underlying factor. Lues is mentioned by Oppenheim, but appears to be unusual. Heubner,* however, says that without doubt syphilis lies in the background of some of these cases, though the connection has not yet been cleared up. (Chronic syphilitic encephalitis, or meningo-encephalitis, however, is by no means uncommon.)*

In the child alcohol plays the very rarest rôle; in the adult, however, chronic alcoholism has been a decided factor, producing a special form of the disease, *i.e.* the *poliencephalitis superior hemorrhagica of Wernicke*).† The possibility of sunstroke and heat stroke as an etiological factor, though probably rare, must be kept in mind. I remember a remarkable occurrence of the latter in Nonne's wards, the case at first being thought hysteria.

In the majority of heat stroke cases and heat stroke from insolation, however, not encephalitis, but edema of the brain, sometimes also of the leptomeninges, with marked generalized passive hyperemia, is found.[a] Rawling, in his study of cerebral edema, also states that edema was found in his patients suffering from "heat effects." The symptoms were headache, usually frontal, worse toward evening, vomiting, ocular changes, slow pulse, rise in systolic pressure, exaggeration of reflexes, slight rise in temperature, more marked during the headaches, and epileptiform convulsions. Several cases showed mental predisposition. Rawling believed the symptoms due to excess of cerebrospinal fluid, and decompressed.* (*Brit. Med. Jour.*, May 4, 1918.)

Encephalitis has also occurred in meat, sausage (botulism), fish,† mushroom, and carbon monoxide poisoning (*i.e.* so-called "ptomaine-paralyses" or "toxic poliencephalitis").‡ Finally, Oppenheim calls attention (No. 1, p. 10) to a non-purulent encephalitis, come upon in individuals who had or once had had a purulent otitis. Yet this matter and connection, Oppenheim states, is not quite clear. In passing, one might for completeness' sake also give variola, mentioned by Moreau[w] and Moritz,[n] as a possible etiological factor, chicken pox,§ mentioned by Heubner, and apparently, rarely, malignant endocarditis and lyssa (hydrophobia).

Besides these "secondary" cases and the "primary" already alluded to (*i.e.* Heine-Medin, influenzal, and "epidemic"), there are quite an appreciable number of instances in which no cause of any kind, either etiologically or pathologically, was dis-

think any diphtheritic case has yet been shown in which the paralyses were due to an encephalitis. He does not deny, however, that encephalitis may occur (*Jahrbuch f. Kinderheilkunde*, July, 1913). The tendency of the diphtheritic toxins to cause neuritis complicates the difficulties of diagnosis. Thus a bulbar paralysis has been described in diphtheria on a neuritic basis. So Oppenheim (No. 1, p 97) also states that it is impossible to say whether an ophthalmoplegia post-diphtheritica is due to neuritis or encephalitis. Extremely rarely diphtheria toxins cause "*a postinfectious psychosis*." In a case of Kühn this lasted for three months (cited by Ziehen).

§ It may be interesting to note in this connection that, though mumps encephalitis appears to be rare, a lymphocytic (serous) meningitis is most common. This was noticed by Massary, Tockmann and Luce in nearly all their mumps cases in soldiers in 1915 (*Cf.* Bulletin de l'Académie Médecine, Paris, July 3, lxxviii, No. 27, p. 6), as also by Herrick and Dannenberg.[s] *Cf.* also H. R. Casparis, A. J. D. Ch., September, 1919; W. R. Larkin, the Mil. Surgeon, January, 1919.

*Typhoid (toxemia) more often causes a meningitis serosa; delirium, however, may be present without such meningitis as an accompaniment to the high temperature, subsiding as the temperature or the disease itself subsides. Such delirium may again persist after the disease has abated, *i. e.* prove a "post (infectious) typhoidal" psychosis. This again may clear up. Finally, besides the possibility of an encephalitis (rather unusual), one may get a typhoid focal infection of the brain leading to "post-infectious imbecility or dementia."[t] Cases have also been described appearing to be an encephalitis (hemiplegia, etc.) which have entirely cleared up and may have been of the nature of an edema (?).[v]

*There are cases of congenital or acquired syphilis in which a low grade chronic process (interstitial or vascular) is going on in the brain, the individual showing no signs or symptoms whatsoever. Suddenly, without any warning, there is an acute "flare-up" with a convulsion or coma or delirium, etc. It may be interesting to mention that a toxic hemorrhagic *encephalitis* has been caused by injections of salvarsan (Zaloziecki, *D. Z. f. N.*, 1913, Bd. xlvi, H. 3., also Reif, *M. m. W.* No. 1, 1921). A Landry's paralysis from Nonne's wards has also been reported from such injection.[r] *Cf.* on syphilis under "Differential Diagnosis."

†Dana states that in about one out of ten autopsies on the brain of persons who died from *acute* alcoholism, he found large foci of hemorrhagic softening with evidence of inflammatory reaction about it.

*Comparing these symptoms with those found in chlorosis, it would appear to us that there was a greater (severer) change present in these patients than mere "excess of cerebrospinal fluid." (*Cf.* Differential Diagnosis.)

†A very interesting case for the psychiatrist is that of C. W. Burr, "Chronic Dementia, Cerebellar Ataxia and Epileptiform Convulsions in a Boy, caused by Ptomaine Poisoning from Eating Canned Salmon," *J. of A. M. A.*, May 30, 1914, p. 1712.

‡In carbon monoxide poisoning the characteristic brain lesion is a *bilateral* necrosis of the lenticular nucleus. Punctiform hemorrhage may occur throughout the white matter. (*Cf.* Hill and Semerak, *J. A. M. A.*, August 24, 1918.) Psychoses with intelligence defect and severest memory disturbance may also obtain—even with subsequent recovery. (*Cf.* Breitung, *Allg. Zsch. f. Psych.*, 76, H. 3.) The report of a case of poisoning by hydrocyanic gas made by Dr. Samuel Lamber is not only highly interesting, but contains a very instructive fact. The spinal fluid in this patient was under normal pressure, but gave a cell count of 207, 45 per cent. of which were polymorphonuclears. This, together with some of his symptoms, would suggest a purulent meningitis. Nine days after, the fluid was clear, 120 cells, 60 per cent. now lymphocytes. Necropsy showed *no meningitis, but distinct encephalitis*, small hemorrhagic areas in the white matter and neuronophagia changes. The cerebellum was most affected. The corpus striatum and thalamus escaped (contrary to carbon monoxide poisoning). There are many other interesting features in this case, the absent knee-jerks, the muscular twitchings (which latter the author attributes to the cerebellum—though we would place the source of this in the cerebrum itself), etc. (See *Neurol. Bulletin*, March, 1919.)

Several cases of veronal poisoning have been described which clinically resembled encephalitis. The patients recovered.

§Sachs mentions an interesting case in which, following a single convulsion at the onset of chickenpox, a (till then) healthy child of 15 months lost its speech and remained thereafter in a condition of complete idiocy. Sachs holds this due to the convulsion, intimating, I believe (by what precedes), the occurrence of hemorrhage due to the convulsion. The possibility of this having been an *encephalitis* (in the light of the evidence we have to-day [and *cf.* what we say under pertussis] cannot, however, be excluded. (B. Sachs, Nervous Diseases of Children, 1905, p. 438).

coverable, even though in some of these (lethal) cases necropsy examination was made (*i.e.* no abnormality whatsoever being found in the brain).

No age is exempt; yet the largest part of this chapter belongs to childhood, the majority of cases being seen in the second and third years. The disease is rare within the first nine months, though it does occur even in the earliest,* and is but uncommonly seen after the fifth.†

Course and Symptoms.—During the course or near the end of one of the above infections, there is a sudden rise of temperature (sometimes a chill), and with this the appearance of *general brain symptoms, i.e.* headache,‡ vomiting, a convulsion, followed by sopor or coma, with delirium after the coma subsides. For a day or two before, prodromata of malaise, headache, dizziness, or somnolence may have been noticed. In children, fever, vomiting, and convulsions almost always occur; in adults, convulsions may be absent, as likewise temperature (the last frequently absent, it will be remembered, in poliomyelitis and poliencephalitis, *i.e.* Heine-Medin disease, sometimes absent in the epidemic form and usually absent in the Wernicke type). The temperature comes down after a few days—though occasionally it may persist considerably longer. At times, yet rarely enough, there are cases in which sudden paralyses are noticed with scarcely any previous indisposition. Holt even mentions a child going to bed as well as ever, awaking in the morning hemiplegic. There may be a single convulsion or a series (general, half-sided, or Jacksonian), after which it is noticed that the child does not use its arm, has a facial paralysis§ or is aphasic;* or this is first noticed after the coma, if present, lets up and consciousness returns. For the most part pareses or paralyses are present *by the second, third or fourth day*, a matter of considerable importance in the differential diagnosis (Ziehen). During the early sopor or coma a tremor may be seen in a limb, or choreiform movements, or jactitations (*i.e.* cortical irritation), usually in the limb later to be found paralyzed. Or weakness in a limb is first noticed, which gradually becomes distinctly paretic and then paralyzed (the paresis or paralysis being accompanied by hypertonus or spasticity). The involvement is for the most part *hemiplegic* (with involvement of the face. Occasionally it is diplegic, rarely monoplegic).

Cases have been described in which, in the course of an acute infection, pneumonia or intestinal intoxication, a child (usually between the ages of 2 and 4) develops a large coarse tremor of the extremities and head, which is intensified by affect, scarcely by active movements, and usually does not entirely disappear during sleep. Occasionally it is half-sided. Occasionally, too, one finds mild pareses, spasticity, and ataxia. From here there are transition forms to real *encephalitis with tremor*. The cases clear up within 2 to 12 weeks. They have been written of under the title of "acute cerebral tremor." Ziehen,† however, terms them the "*tremor form of encephalitis*" and believes they are not different from the forms with paralysis, but rather shade gradually into them. He mentions the possibility at times of a toxicosis of various ganglion cells being the underlying cause rather than an inflammation.

More recently L. Sironi (*Rivista di Clinica Pediatrica*, May, 1918), in a study of *tremors of infants*, suggests that the cause of this symptom seen in early infancy is usually an abnormality in the cortical motor area, traceable in some to toxic infection, in others to gastrointestinal or pulmonary disturbances. Hereditary predisposition seems to play a very decided part. [He mentions, incidentally, that the toxic infection may excite the thyroid and overstimulate its activity, this being particularly apt to occur in malaria.] Still more recently Schippers (*Nederland. Tijdschrift v. Geneesk.* Amsterdam, Sept. 11, 1920, published 5 cases of tremors in children. In one, together with two other children of the family, there was a hereditary familial tremor. In two infants of a year there was an "acute cerebral slow tremor with wide excursions" in neck and limbs, persisted in sleep, exaggerated by excitement. S. comments that such tremors may be one-sided or in one arm or leg, and that there may be spastic phenomena, paresis and ataxia, always preceded by infectious disease or enteritis. *In one case the child grew up feebleminded.* Such tremor may be the first clue to meningitis, hence lumbar puncture should be done. In S.'s fifth case there was evidence of high pressure. Necropsy revealed hydrocephalus with suppuration in the ventricles. Such tremor as an early and single sign of meningitis is rare, yet there is a case (Göppert) on record.

Occasionally abnormal motor phenomena are noticed after the infection clears up. Thus Fürbringer (*D. m. W.* 1889, No. 4) reported a case of post-scarlatinal hemiatheto-choreatic movements due, as he believed, to an encephalitis. It may also be of interest in this connection to mention that recent studies of the pathological anatomy of (infectious) chorea point to an infectious or toxic (Jacobsohn) or septic form (Orzechowski) of a variously distributed encephalitis.‡ Chorei-

*The cases of early infancy—sometimes occurring after severe intestinal disturbance—rarely survive. These cases will be found separately studied by Zappert,[12] also by Finkelstein.[13] In these cases the disease is more apt to be primary and the result of a septic process. Finkelstein, in fact, calls this type "septic encephalitis." The condition lasts one or two weeks, the diagnosis from meningitis being almost impossible. Most of these infants have been premature. In many, according to Finkelstein, the trouble must have begun intrauterine. The brain changes found at autopsy have been very great. (*Cf.* also Fischl's publication [a case of encephalitis in an infant of 12 days], *Prag. med. Woch*, No. 26-28, 1897.) See also in this connection the *Encephalitis interstitialis congenita* of Virchow (*Cf.* W. Ceelen's recent paper [Gehirnbefunde bei Neugeborenen und Säuglingen. Encephalitis congenita Virchow's. *Virch. Arch.* 227, 1920, H. 2.] and the *Pseudotetanus* of Escherich (Traité des Maladies de l'Enfance, Vol. IV, p. 766). An instructive case of this sort is given by O. Witzinger, Klinik des Pseudotetanus. *Zeit. f. Kind.*, Bd. v, H. 6. Here the condition (generalized tonic spasm) began 5 days after a blow on nape of neck. This "latent period" should be borne in mind. Cf. also abscess, "late hemorrhage," etc. Where there is a wound (in very young infants inspect the umbilicus!) *real tetanus* may be the cause. In some tetanus cases there is fever, in some none.

†Gowers found 3 5 of his own cases occurring in the first two years, ¾ in the first three years, ⅞ in the first five. He found them equally numerous in the first and second years. In the traumatic influenza and poliencephalomyelitis types, older children and adolescents were more often affected.

‡This symptom, however, is not as pronounced and severe as in a meningitis.

§This being central, *cortical*, does not involve the eyes—*i. e.* is a "mouth-face paralysis." It does not occur bilaterally. In the primary forms the facial paralysis occurring is for the most part *nuclear*, and hence complete. Occasionally, however, for some unexplained reason (partial involvement "of nucleus"?) the paralysis is not complete. In the epidemic form the paralysis is more often bilateral and includes a partial ptosis, due to involvement of the 3d nerve. For complete *differential* see under "epidemic" form.

*Aphasia is also frequent enough in the cerebral form of Heine-Medin disease; but it never occurs, or but most rarely, in epidemic encephalitis (which is not "cortical").

†See Cramer's article in No. 15. For Orzechowski's full study, see the Arbeiten aus dem Neurol. Institut von Obersteiner, Leipzig & Wien., 1907. Pbl. Deuticke.

form manifestations have been seen in poliomyelitis, but this is very rare. Thus Netter and Ribadeau-Dumas reported a case of paralysis of limbs and choreic movements of the face and protraction of tongue in a six-months-old infant. Necropsy showed typical poliomyelitis.

Cf. also two cases (the sporadic) of *acute infectious myoclonus multiplex*, published by J. R. Hunt.[16] In these cases there was temperature, shooting pain, delirium, *myoclonus* and *myokymia*, but no paralyses. The one autopsied case evidenced neither macroscopic nor microscopic brain changes that could be held accountable for the disease. The remaining (epidemic) cases of Hunt's, save that they were seen during the time we had epidemic encephalitis with us, seem to have little, if anything, in common with so-called "epidemic" or "lethargic encephalitis." Still Strümpell and others mention "epidemic" cases with very similar symptoms[17] which makes it appear that the virus of epidemic-encephalitis also can cause myoclonus.

An instructive case of myoclonus was shown at a psychiatric meeting at Bonn, June, 1911.[18] A man of 59, denying syphilis (wife, however, having paresis), noticed myoclonic movements in the left leg—no other symptoms. After a time sudden paralysis was added. There was spastic paralysis with Babinski and clonus, also decided anesthesia. In spite of the paralysis the myoclonus continued. Lumbar puncture showed no pleocytosis! Nevertheless patient was given antisyphilitic treatment, and in 20 days both the paralysis and myoclonus began to let up. Clonus disappeared; Babinski still present, likewise the anesthesia. "Probability diagnosis" a circumscribed syphilitic meningitis in the region of the cortical leg center. (In the same issue, No. 18, p. 1147, A. Westphal reported on two "odd" cases of *familiar myoclonia*, beginning at the age of 20 or so in two sisters. Westphal did not think the cases organic, yet wishes to separate them from hysteria.)

J. Hoffmann[19] also cites a case of myokymia in a syphilitic, which improved on antiluetic treatment. This patient, 21 years old, had had poliomyelitis at the age of 2½, both legs affected. He acquired syphilis at 20. Soon after weakness and twitching were noticed in the legs, and the myokymia gradually spread to all the muscles (which were not the seat of paralysis due to the earlier polio) up to the neck. In another poliomyelitis case of Hoffmann's, however, fibrillary twitching occurred *in* the paralyzed muscles. Brorström also mentions a poliomyelitis case with twitching in the arms and legs, lasting a day, no paralyses supervening (l. c. No. 30, p. 146).

Finally, *myokymia* has been noted in polyneuritis (l. c. No. 19a.,19 b.) and needs be kept in mind. (For a full discussion of these abnormal motor phenomena see under *epidemic-encephaltis*.)

If the left brain is the seat of trouble, aphasia frequently occurs. Sometimes there is a hemiparalysis of the tongue (which points to the paralyzed side) and conjugate deviation of the eyes and head. Occasionally there is visual disturbance due to involvement of one or both occipital lobes (see cases below). Optic neuritis has several times been seen (Oppenheim), but very rarely are other cranial nerves involved.* *This applies to the general, infectious-toxic forms, which are chiefly convexity or vertex affections.*

Psychic symptoms also occur, irritability, somnolence or sopor and delirium. Occasionally confusion, disorientation and excitable states bordering on mania have been described. Rarely (in adults) the disease begins with acute delirium or confusional states.† Very probably these are cases in predisposed individuals. These symptoms, however, need not be dwelt upon here, as they will be discussed more fully further on.

Keeping this postinfectious-toxic, chiefly secondary, chiefly convexity (vertex) form of the disease in mind, we must now note some special types, several considered from the viewpoint of etiology, several from that of regional involvement.

Influenzal Encephalitis.—The first of these is that associated in *Influenza*. Influenza, like scarlet fever and other infections, has produced secondary encephalitis. The Pfeiffer organism itself has been found in the brain (was, in fact, the first organism to be locally demonstrated in encephalitis). Such (sporadic) cerebral involvement occurred especially during grippe epidemics and often enough to make many observers term this (*i.e.* grippe encephalitis) the most frequent type of encephalitic disease. And now the "new" epidemic form again brings up the controversy through its apparently close association with epidemics of grippe. The influenza infection itself has characteristics we might for the moment recall: its spread in the body is disseminated and diffuse; it has a strong predilection for the nervous system;* its anatomopathological effects consist of many minute punctate ("flea-bite") hemorrhages—found in the various organs, so well demonstrated at times in the membrana tympani of the ear. And just this same diffuse, disseminated, punctate hemorrhagic condition has been found in the influenzal encephalitic brain at autopsy. *It is usually a convexity affection,† also usually involving but one hemisphere, and the motor area of that.*

This brain involvement may occur during the influenza attack, or just as it is clearing up and the temperature has declined; yet more usually, and this is interesting, it appears *after the infection has terminated*, possibly several weeks, even months, after. Suddenly the temperature again rises, there is vomiting, convulsions, possibly delirium, and coma. Lethargy may supervene or a strong tendency to protracted sleep. These symptoms are also noticed in the usual postinfectious type; only in the grippe cases they seem to be very marked when present, very intense, so that sometimes one can scarcely rouse the patient, or, as in a case of Heubner's, finds the condition quite uncombatable. There are cases, however, in which lethargy does not at all occur.

Very probably the psychic disturbances at times noticed after an influenza attack must occasionally (probably often) be attributed to an encephalitic process (*cf.* typhoid above). These may be severe.

---

*This is in contrast to epidemic encephalitis, in which outspoken optic neuritis has very rarely been seen, though slight affection of the discs has several times been reported while pareses and paralyses of other cranial nerves, especially the 3d and 7th are common.

†Delirium is often met in influenza; it is rarely, if ever, mentioned in poliomyelitis, or the cerebral form of that disease. It is not infrequent in epidemic encephalitis, and *is usual* with the choreic and myoclonic forms. It may, in fact, *per se*, constitute a "cortical type" of that disease. We must keep delirium in mind as being possibly only an accompaniment to temperature or toxemia in a (any) disease—especially occurring in nervous, overreactive children. It may occur as a postinfectious psychotic phenomenon, lasting beyond the disease itself. It is a usual symptom of certain poisonings, as with alcohol, belladonna, etc.

*Leichtenstern,[20] after the epidemic of 1890, recognized the fact that this infectious disease, and it preeminently compared with others, was characterized by its intense neurotoxic effects. Leichtenstern at the time also called attention to apoplectiform mono- and hemiplegias (and Jacksonian attacks), occurring on the basis of an acute hemorrhagic encephalitis.

†But occasionally sporadic influenza may also affect the bulbar nuclei, rarely, perhaps (?) the basal ganglia.

Hallucinatory confusional states, lasting for many weeks, even spells of mania have been seen, even in children (*cf.* Heubner, *l.c.*, vol. i, p. 572).

In an adult patient referred to me influenza had been diagnosed three months previous. Besides the catarrhal symptoms the patient had run a high temperature in which she sang and talked. This delirium lasted two months, an irregular temperature persisting all the while. The patient was said to have been decidedly nervous as a child (had fear of the dark and of certain people, enuresis up to 12), and was thus, without question, a predisposed individual. A neurological examination elicited little that was abnormal: the reflexes were strong, r.-l., the pupils were a trifle sluggish (this soon cleared up), the pulse was full and somewhat bounding, but not accelerated, the extremities normal. The gaze, however, was distinctly psychotic, "starey" and furtive. On the mental side the patient was restless, noisy, talked and acted "foolish," as the mother put it, that is, laughed and scowled without rhyme or reason, had illusions and delusions, and especially distrusted her mother, who had been taking the best care of her. Gradually, a month after I first saw her, improvement set in, and a month later she was entirely clear and well.

It appears that the psychopathic effects of influenza may be of all degrees, shadings and varieties. This is especially well brought out in an excellent series of reports of Menninger,[21] out of the Boston State Hospital. Not only is it evidenced here that the toxins of influenza may cause all forms of neuroses and psychoses, but that a normal individual may, through such influenza, become psychoneurotic, manic-depressive, or schizophrenic, etc., as well as the predisposed, and that existing abnormal conditions are made worse, a psychopathy become a psychosis a neurosyphilis a paresis, a moron, an imbecile, etc.

Just to what actual brain process the psychic and psychosomatic changes are to be attributed is not brought out in Menninger's studies. That an encephalitis is here and there the underlying cause, seems, however, apparent, the following case, reported with necropsy, being illuminating in this connection:

The patient, a woman of 43, came down with acute grippe Sept. 10, 1919. Palpitation and a fear of death kept her from sleeping. Taken to hospital, there 15 days, during which period she was agitated, querulous and complaint of pain. Went home was two weeks in bed, then 6 weeks up. Depressed, complained of impaired digestion, intense constipation, and that she could not possibly live. Made many pretended and one real attempt at suicide. Ten weeks after the influenza, brought to hospital. Was agitated, apprehensive. Examination negative, save for absent knee-jerks. On the sixth day after admission she was found unconscious, with a pulse of 140, temp. 104°. So she remained for ten days, when she died. The necropsy (brain examination by Dr. Southard) showed an extensive cerebral hemorrhage, with evidence of many petechial hemorrhages throughout the cortex, bloody fluid in the 3d ventricle and also acute leptomeningitis.

Two very typical cases of *influenza encephalitis* are reported by Högler,[22] the one with necropsy:

Case I. Patient 16 years old. Takes sick Oct. 17 with fever, headache, nosebleed, exhaustion, and coughing (with blood-stained sputum). On the 22d amaurosis abtains. On the 23d patient becomes unconscious. Urine shows albumin. Diazo positive.

Status Oct. 24: Unconscious. Temp. 40°. Subicteric. Multiple little bleedings into skin, especially in upper extremities. Opisthotonus. Kernig. Hyperesthesia of skin. Tonic-clonic convulsions in the extremities, occasionally in the entire body. Rigidity of muscles. Increased reflexes. Abdominal reflex not obtained. Abdomen scaphoid. Pupils wide, react to l. and a. Fundi normal. Pulse 112.

Oct. 26. Exitus. Necropsy: Suppurative bronchitis, abscess in lung, mycotic endocarditis of mitral valve. Metastatic abscess in liver and spleen. Bleedings into skin. *Encephalitis hemorrhagica of left occipital lobe, with secondary hemorrhage, hemorrhage into centrum semiovale of r. hemisphere with softening. Multiple encephalitic foci throughout the brain (including r. occipital lobe).*

Microscopically minute bleedings. The vessels show no wall infiltration, but *severe necroses of the walls, and necrosis of neighboring tissue.* Here and there small accumulations of polynuclear leucocytes, so that one had to think of beginning of multiple minute abscesses. The gray substance was less affected than the white.* [The cortical nature of the amaurosis is to be borne in mind.]

Case II. Patient aged 27. Gradually fever set in with headache, pains in the joints, general exhaustion, coughing and pain in chest. These symptoms for 5 days. In hospital Oct. 13. Dyspnea, unrest, pneumonia. Urine shows albumen. Pupils wide, react to l. and a. Reflexes lively. 16th: temperature high. 23rd: *temperature again, and now somnolence, headache, hyperesthesia* (involvement of brain). 24th: Sensorium strongly clouded. Some stiffening of neck. 27th: Still comatose, tonic-clonic seizures in right half of body, especially severe in right arm, with drawing of mouth to right. These (Jacksonian) spells of several minutes duration, 30 on that day. Following attacks coma severer. Reflexes stronger on r. No Babinski. 30th: seizures decrease, but occasionally trismus starts them. R. up. extr. paretic. Nov. 2: double-sided myringitis. Very soon now the arm clears up; sensorium clears slowly, yet still somnolent on Nov. 19. Still has headache on left. Recovers completely Dec. 7.

In both cases we find the brain involvement coming on several days after a general catarrhal infection had taken place.

An interesting case in a child is found in a report of a group of cases of Heiman's.[23] A girl 3 years old was admitted to the Mt. Sinai Hospital with a history of influenza two weeks previous. Four days before admission the mother noticed the onset of spells lasting about a half-hour and appearing every 3 or 4 hours, during which the child would cry and shout in wild excitement. This continued for several days in the ward. Recovery in ten days. (Details of case not given. Hysteria?)

S. Notkin (*Corr.-Blatt f. Schweizer Aerzte*, Dec. 14, 1918) reported a series of influenza (mental) cases, in two of which acute mania occurred, and in two others a latent dementia praecox was set into pronounced action. E. F. Sanz (*Revista de Med.*, etc., Madrid, Jan. 7, 1919) reports some severe cases arising out of mild influenza. In one case the psychosis took the form of an acute melancholia with suicidal tendency and refusal to eat. W. C. Sandy (*Archives of Neur. and Psych.*, August, 1920) discusses a very extensive series of neuro-psychopathic army cases in a decidedly "brief" way. In 73 cases influenza was deemed a causative factor. Of these there were 32 infective-exhaustive psychoses, mostly with delirium, 7 dementia praecox, several of which were entirely well up to the influenza, 4 manic-depressives, 19 psychoneuroses, 2 with constitutional-, 2 with mental-deficiency, 2 with paralyses of the facial nerve, 2 with neuritis, 2 with cerebral embolism, one with hyperthyroidism. It is to be regretted that these cases were not reported in detail and with data showing on what the diagnosis was made. A similarly undetailed report is one by E. W. Fell (Post-influenzal Psychoses, *J. of A. M. A.*, June 7, 1919). Out of 2500 influenza cases treated at the Walter Reed Gen. Hosp., only 4 cases developed psychotic states which required attention after the subsidence of the fever (and three of these had pronounced pneumonia consolidations). Beside these four, 16 other cases were admitted to the psychiatric wards, in which influenza

*Ziehen (*l.c.* No. 15) points out in his general chapter on Encephalitis that the usual pathological lesion is in the centrum semiovale near the cortex, more rarely in the cortex itself.

played some etiological part. The author divides these 20 cases into three groups, Manic-depressives, 8 cases; Infective psychoses, 7 cases; Dementia praecox, 5 cases. Predisposition seemed present only in the first group (cf. also L. Bouchert, *Rev. méd* March-April, 1919, and S. C. Jelliffe, *N. Y. M. J.*, October 26, 1919.)

Of considerable diagnostic interest, and rather instructive, is a post-influenzal (but not encephalitic) case reported by Langstein[4] in 1912, one which might have been dubiously diagnosed or later misinterpreted, if not attended by so careful an observer. This was an infant of one and a half years who, together with several other members of the family, had come down with bad influenza, the infection severely invalidating its heart (myodegeneration with very considerable dilatation). While under observation, it suddenly developed a complete right-hemiplegia, due presumably to *cerebral embolism*. There was a paralysis of the right face, arm, and leg. There had been no convulsion. On the other hand, "an enormous" painfulness of the left half of the head obtained, which only disappeared after 48 hours. Little by little nearly everything cleared up (now 3 months after the *stroke*), save for some slight spasms, especially in the arm, less so in the leg.

The impression obtained from the recent literature is that the influenza-caused psychoses far outnumber the non-psychotic (somatic) cerebral cases. Why the one and why the other? With the lack of care shown in gathering the anamnestic data in many of the above papers, it is impossible to say whether predisposition will explain this matter. There are other probabilities that come up. Some of the really encephalitic cases have no doubt been rubricced under meningitis, and are missed in these statistics. Still the number cannot be large. We might consider intensity of infection, *i.e.* intoxication vs. infection (with different degrees or forms of pathological process?). Or again electivity of areas involved (Flechsig's?, frontal?) with resulting diaschesis. The answer will in all probability be found in the domain of psychophysics, and in the electivity of cells (groups of cells) in which the *psychic phenomenon* is possible (*i.e.* psycho-physical parallelism), *versus* such in which no *psychic correlate* occurs[2a]. This electivity, it will presently be seen, is a decidedly important factor.*

(*To be continued.*)

SOME OBSERVATIONS ON THE NARCOTIC SITUATION.†

By EDWARD HUNTINGTON WILLIAMS, M.D.

LOS ANGELES, CAL.

About ten years ago the use of narcotics became the subject of popular agitation in the United States. There were good reasons for this agitation. The responsibility for a series of spectacular crimes occurring in the South was attributed to narcotic addiction. And criminal acts in varying degrees of atrocity occurring everywhere throughout the country, and with apparently increasing frequency, were laid at the door of drug habitues. Thus public attention was focussed upon the evils of the abuse of narcotics, and the inadequacy of our legal measures for controlling the situation. As a result, the Harrison Narcotic Law was enacted by the Federal Government on December 17, 1914.

This law was not a hastily conceived statute rushed through as an emergency measure. On the contrary, it was the result of the mature deliberation of persons intimately familiar with the narcotic situation. It was formulated with the knowledge and assistance of medical men, and of medical associations, thus bearing the stamp of approval of the very persons who, next to the narcotic users themselves, were most vitally affected by its provisions. For this law placed restrictions upon members of the medical profession and, in effect, dictated the manner of practising the profession of medicine to an extent scarcely approached by any legislation in recent years.

The law not only transgressed ancient customs heretofore held sacred to the judgment of physicians alone, but made it necessary for every physician to engage in irksome details and exacting clerical work quite foreign to the usual medical régime. All this with the approval and cooperation of the members of the medical profession, who appreciated the importance of and the difficulties involved in stemming the rapidly rising tide of opiate addiction.

Nor was it alone those most directly affected who approved the new statute. Popular approval was almost universal. And, as would be expected in the case of any law having such a background and such a backing, this statute became actively operative from the day of its enactment. Never for one moment has its enforcement been neglected. On the contrary, a veritable army of specially appointed officials—Federal, State, county, and city officials—have devoted their energies to the law's rigid enforcement.

From time to time the various courts have interpreted certain points in the law. And almost without exception these rulings have tended to tighten the net about the narcotic law breakers. There has been no trend toward leniency. So that at the present time practically every prescription written by a physician for a narcotic comes under the careful scrutiny of a competent inspector; practically every grain of narcotic dispensed by every pharmacy in the land must be accounted for to Federal and State inspectors; and a majority of the habitual narcotic users are known to the authorities even to the extent of knowing approximately the amount of drug they are taking and the length of time they have been taking it.

Nor is this narcotic knowledge a mere formality. Prosecutions of offenders who have broken the Harrison Narcotic Law, or are suspected of having done so, fill the calendars of the Federal courts. And other courts are equally well patronized.

In short, the Harrison Narcotic Law has been a popular measure for something like five years, and as actively enforced as is humanly possible.

What is the result of these years of almost unprecedented legislative activity?

The question cannot be answered in a sentence. But it seems to be the consensus of opinion of Federal, State, and county officials who are most closely in touch with the situation, that the number of drug takers and the amount of drug consumed today, after five years of this active legislation, is just as great as, if not, indeed, considerably greater than it was five years ago.

*It is interesting to note that where motor areas are affected we more often get *hypo* conditions (pareses and paralyses), but when sensory areas are affected we more often get *hyper* conditions (irritations).

†Read before the Los Angeles Society for Neurology and Psychiatry, April 20, 1921.

There is, however, a radical change in the method of obtaining opiates by the drug addicts. The closure of the legitimate channels for obtaining narcotics has brought into existence an illicit traffic of tremendous proportions. The elusive underworld "pedler," well supplied with drugs, now exacts his pound of flesh from his helpless victims, and tempts guileless "prospects" with free samples for the sake of future profits. Thus, without vitally affecting the actual evil, we have added criminality to what was formerly simply immorality.

With this situation existing after five years of active legislation it behooves us to take inventory of our weapons and fighting equipment against the narcotic evil. Why has the Harrison Narcotic Act failed to accomplish the purpose for which it is formulated? Certainly this failure cannot be laid at the door of inactivity on the part of officials, or lack of interest and cooperation by the public. Wherefore, it appears that there must be something fundamentally wrong with the inception of the law itself. A law that fails to effect its purpose when vigorously enforced, and after a sufficient length of time to give it fair trial, must be lacking in something not visualized in its original conception. There seems to be no other logical conclusion.

From a medical viewpoint the law has the fundamental defect of not giving sufficient consideration to the underlying cause of opiate addiction. In effect, it regards narcotic addiction as a purely criminal act wilfully indulged in by normal individuals, with only scant consideration to the possibility that disease may be a cause as well as a result of the condition. Stated in another way, the law emphasizes the legal aspect of the problem and subordinates the medical features.

Now, in point of fact, the vast majority of opiate addicts present an abnormal mental and physical condition closely akin in many respects to the condition known as insanity. And our present narcotic legislation presents many features similar to the older legislation for the control of mental diseases.

It is not medical men alone, however, who believe that narcotic addiction is often the result of an abnormal mental state, not merely a "bad habit." The veteran officers of the law eventually reach this conclusion, almost without exception. In the beginning, when their duties first bring the officers in contact with this class of persons, they usually regard the drug addict as a self-willed and responsible criminal offender. Their opinion is based on the popular conception of addiction, not upon practical experience. But later, after they have been closely in touch with every phase of drug habituation, their viewpoint changes almost invariably. Their original conception was based on ignorance; their later point of view is the result of experience. And no one will question that experience is a better teacher than ignorance.

A precisely similar change in mental attitude occurs in persons who are brought closely in contact with the insane. The novice in insane hospital work invariably thinks that a high percentage of his patients are not insane—that "there is nothing wrong with them." But as he gains in experience his viewpoint changes, just as in the case of the officers who are brought closely in contact with narcotic addiction. And thus we find the experienced narcotic officer inclined to deal leniently with the non-criminal type of drug addicts, because he realizes that he is dealing with persons who are not wholly responsible for their shortcomings.

It is apparent, therefore, that the comparison between insanity and drug addiction is not overdrawn. And in this connection we should remember that it is only within the lapse of a century that insanity has been legally recognized as a disease. Christian nations, for a period of more than fifteen centuries, had regarded insanity as a "possession by demons"—a crime. The unfortunate insane were imprisoned and subjected to every kind of cruelty, just as in the case of the vilest criminal. Yet persons continued to become insane, and usually incurably insane, in the face of the most hideous punishments.

America, the great haven of liberty, offered no sanctuary. Lunatics were beaten, imprisoned, chained in filthy dungeons, and specially maltreated here, just as in monarchy-ridden Europe. And as a culminating touch of persecution our ancestors burned at the stake that pitiful little group of old mad women at Salem.

But even this did not stop people from "going crazy." And at last even the law itself stood aghast at its futile folly.

Then a great French physician, Pinel, proclaimed the heresy that insanity is a disease, not a crime. And with the courage of his convictions, and, fortunately, with an influence that could not be disregarded, he struck the shackles from the inmates chained in their madhouse hovels. And behold! many of these mad creatures regained normal reason! The era of rational treatment of insanity had dawned. Lunacy had evolved from a state of incurable criminality to the condition of a curable disease.

There is an analogy between our present attitude toward opiate addiction, and the lunacy situation of one hundred years ago. Insanity was not thoroughly understood then, and naturally the lunacy laws of that time were inadequate and unjust.

The opiate addict, like the psycopath, is an abnormal individual. But in most instances his physical and mental abnormalities are not apparent to casual observation so long as his system is supplied with a sustaining quantity of the drug. When this necessary stabilizing narcotic is withdrawn, however, the abnormal physical and mental conditions quickly assert themselves with absolute certainty.

Yet even when the similarity between insanity and opiate addiction is recognized, our attitude toward the two conditions is utterly different, and is determined by the supposed underlying cause of each condition, rather than by the conditions themselves. We punish the opiate addict because his infirmity is self-imposed, just as formerly lunatics were punished because it was believed that they wilfully associated themselves with evil spirits.

But the present legal attitude is not consistent even if we accept the dictum that the result of self imposed vices should be punished, while unavoidable misfortunes should not. For it so happens that one of the most important and prevalent forms of insanity, general paresis, is the result of venereal

vice—a self imposed condition. At least 10 per cent. of all cases of insanity are attributable to this vicious cause. Yet the law makes no distinction between paretic patients, with their virtually self-imposed disease, and any other types of insane persons. The paretic is not punished, although in acquiring the specific infection which is the cause of his condition, he gratified a wilful indulgence scarcely more compelling, and generally regarded as for more reprehensible, than the craving for a drug.

It is evident, therefore, that the cause of insanity does not influence the legal attitude toward this disease. Such is not the case with opiate addiction. A drug addict is a malefactor in the eyes of the law whether he acquired his habit through pure viciousness, or whether, as is often the case, his addiction was thrust upon him unwillingly, as in the case of many maimed veterans from France.

It is true that there is a somewhat vaguely phrased distinction in the legal attitude toward persons who are criminally insane and other demented individuals. All insanity is disease, but in some States special hospitals are provided for the care of persons sufferings from "criminal insanity." But even so, a very great distinction is made between this type of insanity and ordinary criminality. No such distinction is made in the case of drug addicts. Yet we know that there are addicts whose drug taking makes them criminals; and others who regard criminal tendencies and criminal acts with just as great abhorrence as the highest type of normal individual. It is just as inconsistent to put these persons in the same class as it would be to place ordinary criminals and insane criminals on the same level.

The important thing about the existing narcotic laws, however, regardless of inconsistencies, is the fact that they do not appear to be getting adequate results.

One modification of the present law that naturally suggests itself is to increase still further the scope and stringency of the statute. But it would seem that this is scarcely possible without curtailing the legitimate use of opium. And opium, bear in mind, is our most useful and most important drug. Curtailing its legitimate use would cause untold suffering among countless numbers of innocent persons afflicted with painful diseases. These persons far outnumber the addicts. So that even the complete elimination of this relatively small handful of drug habitués would be scant recompense for such a sacrifice.

A less objectionable plan would be some slight modification in the existing narcotic laws tending to emphasize the medical side of the narcotic problem. There is nothing novel in this suggestion. Indeed, a practical step in this direction was taken in certain cities recently. For example, the Narcotic Clinics conducted in the cities of Los Angeles and San Diego for a brief period in 1920, were based on this principle, and produced results that were encouraging, to say the least.

The Los Angeles clinic was started as a department of the Board of Health, with the approval and assistance of the municipal authorities, for the purpose of giving preliminary medical treatment to the narcotic addicts. This clinic endeavored to supply persons who required the constant use of an opiate with the necessary amount of their narcotic in gradually decreasing doses and at a nominal price. It was conducted by physicians detailed by the Health Commissioner, and under the immediate direction of a Narcotic Board composed of prominent physicians, public spirited citizens, and Federal, State, and municipal officers who volunteered their time and services.

It was not the purpose of this clinic merely to supply the opiate addicts of the community with narcotics. On the contrary, the clinic was established for the purpose of medical treatment, with gradual withdrawal of the drug, and final cure when possible. Complete cure by this method would not be possible in most cases, of course; but it was possible to reduce the amount of drug used, and improve the patients' physical condition so that they could be treated successfully in some suitable institution at the proper time.

The things actually accomplished by this clinic attained, in a measurable degree, the object for which it was created. During the five months of its activity more than five hundred drug addicts applied for treatment. It was a motley company representing every walk and condition of life. Every degree of financial status was represented, every shade of dishonesty, as well as every grade of intellect. Some came from purely criminal motives, others with the exalted purpose of being cured of their habit. Still others, in the hope that they could escape the clutches of the illicit peddler and his extortionate prices.

A record of the obstacles that had to be overcome in putting this experimental clinic into practical running order, the mistakes that were made, the trickery and deception that were practised, as well as the honest endeavors of the deserving addicts and persons suffering from painful bodily afflictions, would make a volume of intensely interesting and variegated narrative. But the important things accomplished may be summarized in a few paragraphs. For one thing, illicit peddling was reduced to a minimum. When the patient could get morphine honestly for ten cents a grain, why be dishonest at ten times that price with a good chance of landing in jail into the bargain? The peddlers complained, almost openly, that they were "being ruined" by the clinic.

To the class of persons suffering from painful afflictions, such as tuberculosis and cancer, whose condition made the continued use of an opiate an absolute necessity, the clinic was a veritable godsend, for it enabled them to procure their necessary drug at a reasonable price and in a legitimate manner. Thus they were able to reduce the amount of the narcotic, since, curiously enough, the uncertainty of being able to get a supply of the drug always tends to make the addict use more of it.

The clinic made it possible for several individuals to engage in honest occupations for the first time in many months. Heretofore, the uncertainty of the source of supply, and the ruinous prices demanded by the peddler had kept these patients in such a state of physical dilapidation that they were unable to work. Thus the clinic enabled many of these victims to again become honest bread winners. Several of them were now able to provide for their families and again live in a respectable and self-

respecting manner. And meanwhile their general health was improved by the gradually reduced doses dispensed at the clinic, and the release from the harassing anxiety about obtaining their drug.

It is a fact well known to persons familiar with the subject, but not appreciated by the generality of people, that almost every drug addict wishes to be freed from his bondage. In many instances the desire is an inadequate and feeble one, of course, while in others it is insistent and compelling. The members of the clinic exemplified this in an amazing degree, all things considered. Within two months after opening the clinic, twenty-four individuals had made earnest application to be placed in some institution for the final treatment and cure of their addiction. And it is most illuminative that after the clinic was closed, no less than twenty-six persons were given this curative treatment in private institutions from the accumulated funds; and fully as many more had filed applications for taking similar treatment and were bitterly disappointed when they found that no more funds were available.

This alone, the fact that half a hundred persons out of a total of five hundred, were sufficiently earnest in their desire to be cured that they were willing to surrender themselves for radical treatment, is convincing evidence of the usefulness of this experimental clinic.

Moreover, the clinic enabled the officers to determine pretty accurately the number of drug addicts in the community, particularly the class of drug takers likely to become a public menace. And the surprisingly small number of these individuals seems to refute the popular idea that drug addiction is running riot in our communities.

The fact that so many of these clinic patients were anxious to take a final curative treatment in some proper institution, and that such a relatively large number of them actually did so is an indication of what might be accomplished with a clinic having hospital facilities at its disposal. Such an arrangement is, of course, the one now in vogue for treating almost all physical ailments; and even mental diseases are now so cared for in certain favored communities.

A similar arrangement, modified to meet the various conditions, would put the legal and medical authorities closely in touch with the addicted patients and with the narcotic situation, in a manner similar to our arrangements for controlling other serious diseases, such as tuberculosis. This factor alone, it seems to me, justifies the reestablishment of clinics along similar lines to the experimental ones tried with such a measure of success in Los Angeles and San Diego. Undoubtedly great modifications would be necessary. But great modifications are always necessary in any progressive experimental work.

In addition, some special hospital provisions should be made, just as in the case of insanity. And there should be some governing body of specially qualified medical examiners to determine the requirements of each case similar to the medical commissions that determine the status and dictate the treatment in insanity cases.

Unlike the existing laws governing insanity, however, the final decision about any case should not be left to the judgment of juries composed of laymen, for the average layman knows less about opiate addiction than he does about the psychoses. And one can scarcely expect intelligent assistance and cooperation from any body of men who know practically nothing about the subject they are called upon to decide.

Perhaps the best practical solution of the whole narcotic problem would be to place it unreservedly in the hands of the United States Public Health Service. This would bring it under control of intelligent physicians who also have legal authority to enforce any clinical or custodial measures that seem necessary.

In any event, the narcotic addict is with us, and like the poor, and the bad, and the unfortunate, he is likely to remain with us. Only the visionary idealist, or persons ignorant of human nature and of human history, can believe otherwise. No great compelling human vice or disease has ever been completely stamped out. And the best that we can hope to do by our most concerted efforts, for the present at least, is to reduce narcotic addiction to a state of reasonable control.

CONCERNING THE HEALTH PROBLEM.

By FREDERICK E. JACKSON, M.D.

INDIANAPOLIS, IND.

UNIVERSITY OF INDIANA SCHOOL OF MEDICINE

THE solution of the first part of the health problem, and by this problem is meant a more desirable relationship between the State, the patient, and the doctor, is dependent upon the education of the doctor. The solution of the second part of the problem depends upon the organization of the medical profession. These parts are interdependent, the educational part determining largely the organization, and the organization to a large degree determining the extent and kind of education to the individual doctor.

Any prevalent, thoughtful conception of medicine includes the general practitioner, the surgeon both special and general, and the specialists. Besides these are the special teachers and investigators of disease, and the affiliated professions of nursing and social service. Practice is confined to homes, offices, and hospitals.

The patients are divided economically into three classes, those unable to pay for any part of medical service, those able to pay for a part, varying from a small part to all excepting special fees in diagnosis and treatment, and those able to pay in full.

Among the organizations concerned are various charitable and fraternal organizations, insurance companies, industrial organizations, public health nursing associations, social service departments, municipal and State boards of health, various governmental departments and other agencies. In some indefinite position but with an undesirable relation are the osteopaths, the chiropractors, the self-styled christian scientists, and those who are opposed to any health system.

All this and these are included under one government called a democracy in which each individual believes to the uttermost in personal liberty and the majority of whom believe with Gladstone that "In the health of the people lies the strength of a nation," with Disraeli that, "The care of the

health of the people is the first duty of a Statesman," and with Franklin that, "Public health is public wealth." A vast majority of people believe these quoted remarks but through fear, ignorance, jealousy, and selfishness they have not solved the health problem. Many partial solutions have been offered but excepting parts, due to the unfairness not much progress has been made. Results prove that every attempted solution has been ill-considered in some respect, and that each proposition has been given with some special advantage to some class or organization other than the medical profession, the very profession which as its output produces the gain sought by the solution. In every case the profession has been treated more or less as a chattel, bonded, mortgaged into slavery, and given no encouragement for its future.

Few realize, or realizing fail to take into consideration that the health solution must accomplish two specific acts;—first, give the opportunity for health to every individual, at the same time protecting every individual against disease from those who do not avail themselves of this opportunity; and second, give encouragement to the profession of medicine by rewards commensurate with its services.

An industrial organization confronted by such a problem would solve it immediately, even though it involved the formation of a monopoly in order to make certain sufficient returns from the investment. It would absorb into the trust all competitors as they arose.

The solution of the health problem on a comprehensive scale has heretofore seemed to be the problem of no particular group. Yet each interested group has solved or thought it has solved its health problem, or has a proposed solution, and in each instance the solution is not only unfair to the medical profession but the medical profession has not been seriously considered. In many cases even those considered to derive benefits from the solution have been given a farce which they upon serious reflection do not want. All this has been done because health is not worth money!

Certain lodges for a small yearly due have undertaken to give a qualified amount of medical protection. The very fact that the yearly expense to the member is small is a guarantee that his doctor is underpaid for his services. If the lodge member will only reason from his own inclination he will conclude that his medical protection is not of the best for he knows that he, himself, will not give competent service when underpaid. The doctor being human he cannot expect more from him. The fact exists that in most lodges the medical job is farmed out to some one physician or layman for a certain sum. He in turn contracts doctors on small salaries to do the practice, keeping the larger amount for what he considers his more brainy service. Anyone can see that lodge practice in general is unfair both to the doctor and to the member. Such contract practice in no ultimate way solves the health problem.

Insurance companies are organized for profit. Medical service both to the community and the company form a bulwark against losses to the companies. Their basis for existence rests on the element of risk. Good health decreases the element of risk thereby decreasing the desire for insurance. This is shown by the inverse ratio existing between the state of health of the community and the removal of risk and the profit of the company. As the standard of health rises, the span of life increases, and the desire for insurance lessens. This increase in health postpones the fulfillment of the insurance contract, adding profit to the company but the decreased desire lessens the volume of business. The profit might bear the same relation as before if it were not for the ever lessening demand and the competition in the insurance field. The competition compels an increased effort to double the volume which in the face of the lessened demand can be increased only by lessening the cost of operation and insurance. An increase in the rate of insurance with the already decreasing demand would plainly defeat the purpose of the company. The doctor being considered only a servant in the formation of their profit, while still performing the same service necessarily must receive less consideration. These companies are so soundly organized that regardless of the fate of the insured the companies profit. Were the solution of the health problem able to remove the element of risk, insurance companies would have to go out of business, for their offerings would be no more desirable than many other forms of investment. Theoretically insurance companies cannot be interested in solving the health problem.

However true this supposition may seem it is erroneous. The reasoning is mostly theoretical for the element of risk added to other individual reasons as to why insurance is desirable can not be removed. This dissertation, however, serves to show that insurance companies, organized for profit, consider the doctor merely as a servant instead of a partner in the making of their profit. Their ethics being that of survival through profit contradicts that of true medical science which craves early death, through removal of the cause of existence.

Insurance statistics will aid in solving the health problem but they are the by-products necessary to the existence of a purely profit-making institution. While insurance companies may aid in bringing the opportunity for health to an increasing number of people the position necessarily given the doctor due to the nature of the organization will not alter the relation of the doctor to the community through their solution of the health problem in such way as to greatly encourage the profession.

Probably the most that charity workers and charity organizations have to offer the medical profession is an ever increasing burden. Each annual report points with apparent pride to a greater number of paupers aided. Such increase is seemingly observed as conclusive proof of added efficiency and justification of their system. These reports do not state that the charity worker is salaried, that every article of food and clothing given had yielded its normal rate of profit, that the fuel and rent were paid for at what ever rate of profit could be manipulated, but that the medical profession had donated its services. Not only will every doctor recall his free work to municipal hospitals and dispensaries, but also many cases referred to his private office under the pathetic plea

of the diplomatic salaried charity worker. When John Jones through misfortune or profligacy allows his family to starve, the collection is taken and food bought. When the children are sick the blessed doctor has the privilege of carrying John's burden without pay. Such charity system might make of the doctor a more divine man provided he can live under such without becoming internally vicious, but charity seems not to realize that a doctor's services bear the same relation to himself and patient as coal to the consumer and producer.

It is not quite fair to all social service workers and organizations and public health nursing associations to acquiesce in the charges of some that they have done nothing beneficial toward a proper reconstruction of the ideas of the public toward medicine and the doctor. Some of them have helped much from an educational point of view. They are, however, unless made up of volunteers from the sympathetic rich, salaried workers, dealing with the poverty stricken individual, thinking mostly that they must champion the rights of the poor against the medical profession instead of the rights of the poor against a system, or rather lack of system. Too much energy is used in prying better medical service out of the medical profession in favor of the patient instead of trying to get a new relation between the doctor and the public. They are mostly unconcerned as to whether they get more dispensaries with free doctors, State medicine with salaried doctors, compulsory insurance, in fact they are concerned about anything which promotes the interests of their organizations. Social service does not include in its function and organization any solution of the health problem. The medical profession is inclined to place serious charges against these organizations. While to some extent these organizations may be making grievous mistakes they are not unforgivable. The chief fault lies with the medical profession for not having enough constructive lime in its constitution to compel right relations. Social service and public health nursing associations bring better health conditions to the individual patient but very little do they improve the relation between the medical profession and the public.

Industrial organizations are primarily seeking returns from the investment. Apparently they are only now realizing the great expense from the inefficiency of afflicted workers. While this is especially realized in the inefficiency from venereal disease it applies to those afflicted in any way. Observation indicates that industry looks to the clinic or contract system, that it sees the greatest good in the free dispensary, the free hospital, the free treatment health center, or health department clinics.

One manufacturing concern, at a cost of $5,000 to $6,000 for installing a clinic for venereal diseases, reports a return of $40,000 from the investment. It will do no one harm to reflect upon the ultimate destination of this $40,000.

The U. S. P. H. Service has installed clinics for venereal diseases over the U. S. The department is not so sacrosanct that one should apologize for saying that what it has done has been, if accurately and fully accounted, at considerable expense, that it has added nothing to the knowledge of the treatment of disease, that it is promoting a system detrimental to the medical profession, that its ultimate results are questionable, and that its only good has been accomplished through compulsion and supervision, plus education. Education is a duty, compulsion and supervision are not necessarily restricted to the clinic system, but the quantitative clinic system is a breeder of routine treatment. Successful treatment of any disease is personal and individual.

Profit-seeking industry, whether it looks to the different health department clinics or to private clinics, offers no encouragement to the medical profession. It wants increased production but it looks to the medical profession only as a tool to this end. It will subordinate the profession to industrial organization, if it can, in order to produce larger returns. It fought compensation for sickness and accidents resulting from employment until it saw it could add the expense to the cost of production.

Economics assign man as the chief factor in production. The principal qualities which determine his capacity as a producer are (1) health, (2) physical strength and endurance, (3) intelligence, (4) judgment, (5) ambition, (6) energy, (7) perseverance, (8) imagination, (9) mechanical ingenuity, (10) technical knowledge. These qualities are either inherited or acquired. A cursory glance at the order of the qualifications of man in his capacity of producer will visualize to any one the prime importance of medical science. The circumstances influencing health and strength are well understood. The doctor, second to man himself, is the most important factor in production. Considering this relationship, some one in figuring the proportional economic rewards has been grossly incompetent in mathematics or illogical in reasoning.

The Red Cross, perhaps the largest charity organization in existence, is attempting something in the field of public health. Just what that attempt is and what the ultimate aim is no one seems yet to be able to understand. It is quite doubtful whether the directors themselves know definitely. Being an organization based entirely upon charity, it would probably be wisest to confine its operation to its original field of emergencies. When charity enters the competitive field of man's productive labor it is the proper time to withdraw the charity or for men to cease competing, withdrawing from the field and leave it to the pauperizing influence of charity. It is not sound economics nor socially just for any organization existing on charity to enter into competition with any productive or essential class. For any work other than that which the Red Cross has formerly done, it should make a public program. Such program under this organization can offer only contract medical practice which the ethics of the medical profession condemns.

Boards of Health, either municipal or State, have so much administrative work to do that it seems inadvisable to expect them to solve the health problem satisfactorily to the practising physician. In many cases these boards are composed of men entirely unappreciative of the problems of the attending doctor. It is a deplorable fact that some medical men are constantly grasping for power over other doctors, attempting to centralize into an autocracy or rather a bureaucracy the medical profession and practice. It should be the attempt of

every board of health, so far as not conflicting with their duties of protection, to maintain neutrality, to restrain bureaucracy and remove where possible the baneful effects and unjust burden of charity with which the medical profession is loaded.

Why should the profession shoulder this burden of charity? Because it is a question of health? As much so are good shoes, meat, bread, fuel, clothes. As a matter of health these essentials are just as important as a charity doctor. It seems there is made a great distinction between the refusal of the doctor to make a professional call on a charity patient and the coal merchant's refusal to sell three dollars' worth of coal to the same patient. The only reason such distinction can be made is on the basis of different principles governing the ethical relationships. But isn't the State guilty? Should the State permit a large class of its citizens to rest snugly upon the backs of another class? Should the State at the same time enter into competition with this already over-burdened class? There can be only one answer. That answer is "No," everlastingly "No!" The State exists for the individual. The paid representatives are servants of the people and these servants are duty bound not only to maintain equality of opportunity between individuals but also to prevent any essential class from being ravaged by another class. This duty has not been entirely fulfilled in the field of medicine. Perhaps the failure cannot be charged entirely to the State officials but more to the medical profession. While working always with the highest ideals, improving its members by increased requirements, striving in every way for the betterment of the human race, it has not consistently directed its organized energy to any attempt to protect itself as a class nor offered any comprehensive, constructive program for a solution of the health problem. Better health and better health education are being brought to the people but the profession is failing to insure the opportunity for health to everyone, to protect everyone and to perpetuate itself independently and with pride in its accomplishments.

The health problem, if it really exists, must be solved. And it either does exist or the socialists, social workers, and bureaucrats are making a concerted attack upon the medical profession in the creation of a new division of labor from which they expect to derive many good paying jobs. It is not plain as to why these self-styled promoters of the advancement of society make their chief attack upon the medical profession instead of upon the economic system, drug store syndicates, legal system, etc., unless it is because they think they have found in the medical profession the weakest organized opposition. This attack is unjust, probably not entirely altruistic, and unless diverted will in the end bring only grief to the attackers, the attacked, and the championed.

A problem, and it may as well be called the health problem, does exist. If nothing else has placed this problem squarely before the community and the profession the results of the examination of men under the conscription law has shown it in bold relief. Not many of the medical profession will fully agree with the dean of one medical college when he says, "when a State sees to it that only those doctors who can have a good effect on the community in which they practise are allowed that right, just so soon does it begin to remedy the weaknesses shown in the report of the government of the country on our men."

Acknowledging as a fact that the medical profession can be improved both morally and intellectually, surely the dean does not pay himself much of a compliment as an aid to the government or the community. The criticism for so many defective men, if it must fall upon the doctor, should not fall so heavily upon an unskilled profession as upon the lack of a constructive health system in which the doctor can fully use his skill. It is not the fault of the profession that there is a lack of hospital opportunity for every patient in such need, that there is not a competent nurse for each patient requiring a nurse's attendance, that there is not a qualified social worker for adjusting the social side of the pauper family and aiding the doctor in his therapeutics, nor that every qualified doctor cannot get the advantage both for himself and patient in every municipal or State hospital. Neither is it the fault of the profession that society considers the man or woman who knocks another man or woman in the head with a club a fit subject for a penitentiary sentence while considering with the bureaucrats that if the same man or woman transmits syphilis to another, he or she is a proper subject for free treatment and free board and bed in a hospital, one act being a crime punishable by society, the other act receiving one of the highest awards of society.

An indefinite minority of physicians and social workers in every program for improving public health attempt not only to carry the suggestion but to force the commitment of the government to compulsion and entire control. It may be an honest belief that this is necessary for success in public health, but such a socialistic program should be carefully studied as to its effect upon the profession, upon the patient, and upon the army of interested propagandists before any such system is forced upon the nation. Free health clinics, an untold multiple of social agencies, charity, free nursing, government control and compulsion, government bureaux, autocratic centralization, paternalism, political machines, is the composite picture contained within the entire range of vision of these advocates. Such tendencies and teachings propagate a Prussian autocracy with its doctrine of "verboten" and "mussen" only to end in socialism and bolshevism.

Health and protection of life in and from disease are precious and necessary to man's life. Because in them lies the wealth of a nation they are worth money. The profession which brings each year increasing strength and wealth to a nation is deserving of a health system which not only gives health and protection to the people but one which also satisfies the just ambitions of that profession. Tender minds and soft hearts, swivel chair health bureaucrats and politicians will not produce such system. Neither will the miserly bloodthirsty Doctor Shylock produce it. Such system should be the result of studied effort. Actual investigation by competent unbiassed students of the faulty systems of European countries should be made that their socialistic mistakes might not burden our

people and pauperize them as well as the profession. Such committee should include men and women experienced from every angle of the problem. But the part that concerns the medical profession chiefly is that any such group must include doctors who are thoroughly appreciative of every problem in medical life.

Production, Manufacture, and Transportation are being increasingly developed in this country. Such development will continue regardless of whether the medical profession solves the health problem or whether these industrial divisions will thrust some problematical solution upon a supplicating and procrastinating profession. The health problem belongs rightly to the medical profession. This is the portion of man's burden which the medical profession must carry. From this it can not rightfully escape and the successful adjustment of which will be its answer to society for its stewardship.

As a first step in suggesting a plan for the health solution it may be well to restate that such solution must bear two specific results. One is the opportunity for medical care to every individual who cares to accept, at the same time protecting every individual who chooses medical attention against those who do not choose or believe in medical science, and second, the encouragement of the medical profession to renewed energy in the development of that science by sufficient remuneration for its services. If medical science cannot prove beyond doubt that it is through this science disease is conquered, and that through medical practice as developed by medical science and not through the deceptions imposed upon the imaginations by ignorant charlatans national wealth is created, then the medical profession as an embodiment of medical science has no claim for economic remuneration nor claim for recognition as an essential division of society. If this were the largest problem the medical profession had in order to get a successful health plan the solution of the health problem would be arrived at in a day. All it would have to do is to point to diphtheria, smallpox, yellow fever, syphilis, typhoid fever, and many other diseases in which rapid strides have been made toward their eradication or cure. As to specific jobs it would point to the job it did in the building of the Panama Canal as opposed to the job of which it was capable a few years earlier, as to the job in the World War as compared to its work in the Spanish-American War. It takes no more than a semi-intelligent mind to see that medical science as practised by the medical profession, and not the quackery of ignorant cults who continually fight the profession, made possible the successful accomplishments of such great efforts. Sad to say it is more a problem of overcoming ignorance, prejudice, and the fear that the returns are not worth the outlay of money. Since it is not possible to overcome these obstacles in a day nor probable that they will be in the near future, and since it is necessary to improve our health system in order to increase national wealth, a workable system must be devised to satisfy and protect all according to the many ideas of individual freedom and of democracy. Society may not have a questionable right to force treatment upon an unwilling individual, but it certainly has a right to protect itself against such individuals. If society has a right to say the criminal shall forfeit his rights to freedom and must pay his way in some penal institution it is not far to reason that society has the same right to restrict the freedom of any diseased individual who when possible must also pay his way in some institution while such disease proves a danger to society. While at the present time it would be too radical to say venereal disease is prima facie evidence of a criminal act a rapid advance in such direction would lead to a lessening of such disease. Marriage laws protecting the individuals so far as medical science can protect them can be passed and if the State has the right to say who is competent to practise medicine it certainly has the right to say who is competent to offer the protection to the marriage applicant. Not only can such law apply to venereal disease, but also to mental, pulmonary, or any contagious or transmissible disease. If the State can create boards of physicians to examine the competency of graduates of medicine to practise, it can, if desired, create boards to examine the qualifications of doctors to treat any special disease. Marriage being an institution encouraged by the State, it is no more than right that the State pay the fees for one marriage.

There are three classes of medical patients. One class consists of those people financially able to pay for all service. To this class the State need pay no attention excepting to protect them against others and others against them. Such duties fall to the executive functions of State and municipal boards of health.

Another class consists of those who are able to pay for all ordinary service but who are unable to meet the expense of prolonged sickness, hospital fees, fees for special diagnosis, as laboratory and x-ray, or for the services of competent specialists. To this class the State owes a larger obligation. The State should see that there are sufficient hospitals where the communities are not able to build them, and should encourage the building of hospitals where the communities are able to build them. A hospital in every county would be ideal, but where impossible for financial reasons three or four counties might unite in building one hospital. State aid to the poorer counties is just as feasible in public health as such aid in public education. In these hospitals special services could be had when necessary and the community or State should make up the difference between what the patient could pay and a legitimate fee. In many poor communities perfectly respectable citizens are unable to pay for all the medical service they should have. This may be due to the nature of the service, or to distance from the doctor, or various other reasons. If the health and happiness of such citizens add to the wealth of the State, then the State owes something to the individual in return. This return can be given in health, education, and protection.

The third class consists of those unable to pay for any medical service. Each individual in this class, so far as health is concerned is a ward of the community. This is not necessarily a disgrace to the individual nor a criminal state of being. The blind, the deaf, the dumb, the epileptic, the insane, unless exceedingly fortunate in money, are con-

sidered without reproach wards of the State. Every child in a State educational institution may be regarded as a ward of the State. In many cases these children are forced against their will to attend school. These patients are not sick because they want to be sick and will continue to be sick against their will unless the socialist push the State too far into insurance, in which circumstance it is safe to say from the experience of England, Germany, and Austria that fifty per cent. of the sickness will be malingering. When these patients are working they are filling a permitted place in society, producing either a normal or abnormal profit for some one. This adds wealth to the State. It is essentially the duty of the State to care for them when ill. The tendency seems to be now to build health clinics placing salaried doctors in charge. Such system is unfair to the medical profession and unfair to the patient. If this class were small, or if entirely without self respect, the clinic would be all sufficient. But it is probable that not more than 25 per cent. of people are able to pay for all care. This makes 75 per cent. as the wards and partial wards of the State. Every doctor knows that his clientèle consists of those who like him and with whom he has been successful. To deprive 75 per cent. of the people from a free choice of their doctor is unfair to the patient, and unfair to the medical profession. Such system will eventually make of the majority of doctors a salaried class without much impetus to do good work. Such practice leads to careless routine, instead of competent, individual treatment. Such system will strike at the time-honored ethics of the medical profession. Some there will be who will say it is time to break away from the ethics of the past. But before this is attempted there must be a better understanding on the part of the layman of the history, reason, and philosophy of the medical profession, and then there will doubtless be no breaking away.

Perfectly true it may be that something and some one must improve the relation of the doctor to the State, but such relation must remove the suspicion of intervention by the State, and leave the practitioner unfettered and independent.

Such conditions will be met by the State's doing away with free clinics where patients congregate in the hands of a few overworked, half paid doctors, continuing the present system of private practice and private relations between doctor and patient, but the State paying the doctor's bill instead of the patient. In such system both the State and the doctor should be protected against abuse. Here comes in the proper sphere of Social Service. It protects both the State and doctor and acts as a social physician to the State patient either independently, in conjunction with, or under the direction of the physician as the case may require. Patients claiming State aid could easily be required to register for investigation in some social service station, receiving a card if worthy, being permitted to choose his own doctor, on whom the State's board had passed as qualified to give such service as the patient was in need. Such would be a great encouragement to the doctor to continue to grow, also aid the doctor financially. In case the patient needed home treatment he could call his doctor as at present. Where a nurse is needed the public health nurse should be at the command of the doctor in such State system. The public health nurse and the social worker, if properly educated and trained will more than pay the State for their services in the protection they offer the State and in the increased earning time to society which they with the doctor will add through their services to the patient. They in their mutual contact will help Americanize that class of citizenry most in need of Americanization. Many cases otherwise needing hospitalization will with the help of the nurse and social worker not need to leave the home.

Where it is necessary, the State should see that the patient has access to the hospital. In such case the family doctor should not be compelled as he is today to lose contact with his patient. The family doctor is the back bone of public health. He should be qualified to gather up the early cases and know what to do. If he loses an intimate connection in the hospitalization of his cases, he has nothing to carry back to his community, the very source of all reasons for the existence of the hospital.

In doing away with clinics some one may object on the ground of destruction of teaching material to medical students. Such objection can easily be met by permitting the medical school to have a clinic supported in the same way by the State for the State patients, the State also permitting if desired any one to receive treatment at the teaching dispensary and hospital in payment of a fee, but the State should not take out of the hands of the practitioner the patient whom he is willing and competent to handle for a reasonable fee.

For the purpose of special diagnosis and treatment either a reasonable fee can be arranged for the doctors prepared to do this work, or arrangement for full time doctors at the hospitals. Specialists can be used through the family practitioner. Such system herein suggested will require better educated doctors but the system will be sufficiently conducive.

Many questions will be asked as to details in regard to such system of medicine, especially in regard to the cost to the State, the position of many interested individuals and organizations. State and municipal boards of Public Health will necessarily concern themselves with a different part of the problem of health. Industrial disease and accidents, rightly placed under the cost of production, can be easily arranged for. There may be some necessity for the rearrangement of organizations, the elimination of some, but it will be better to unscramble and reorganize now than to wait until the system becomes worse than a Chinese puzzle or an Egyptian palimpsest.

The medical profession must come out from behind its intrenchments of the past, realize that the development of the country not only demand but will enforce new relations between the public and the doctor, that it cannot sulk in its tent and expect other organizations to settle this relation perfectly satisfactorily to it, that it must take its share of responsibility both in the interest of the profession and the public, and that the only way this can be done is in full cooperation with, and in lighting the pathway for, every organization and person concerned. The medical profession should come together with competent leadership. This can be de-

veloped out of the medical societies, making sure of wise spokesmen.

This paper in no way means to be unfair to organizations or to persons, not to close but to open discussion, not to harm but to help, not to lesson but to add interest to this vital question of the solution of the health problem. The medical profession must awaken, it must not become enslaved to politictians within or without the profession, to cranks, to bureaucrats, to members of those organizations created as therapeutic aids to the profession, and whose members due to an unscientific foundation become psychopathic, over emphasizing every newly acquired fact, or subjugated to any profit making organization.

There remains, however, one charming beauty in American life, that in the supreme test, life, the good of humanity, the rights of man take precedence in the ideals of the American over the rights of property. So it is not beyond the truth to say that any group regardless of temporary disadvantage to it when shown correct values will decide rightly.

Small groups in ignorance or selfishness often cast thick shadows over truth permitting only soil devastating tendrils to grow into woody plants. These plants can never grow into giant trees for the germs of corruption and decay omnipresent in darkness permit only the growth of shrubbery without verdure. Sunshine will soon drive out these germs, the propagandist of selfishness, ignorance, and early decay in the social order.

There must not be in the plea for suffering humanity a monopoly of producing or essential minds. If medicine is not productive, if it is not essential, then it must be abolished. But if it is essential it must be as untrammeled as private ownership and have perfect freedom of initiative.

CHLOROSIS A TOXEMIA NOT A PRIMARY ANEMIA.

By S. R. SALZMAN, M.D., F.A.C.P.,

TOLEDO, OHIO.

CHLOROSIS, or anemia of girlhood, is a condition not infrequently met with by the physician. It has been quite extensively studied, yet nothing very definite as to the etiology of the condition has been brought forward. A great many theories have been advanced, none of which has satisfactorily explained the symptom-complex which is usually present, nor the manner in which iron therapy has brought about an improvement in the condition. Because anemia of various grades is present in the majority of cases of chlorosis, it has been classified as a primary anemia, without any definite proof to bear out this classification.

Virchow assumed a congenital defect of the vascular system. Iron therapy could scarcely be a specific in the presence of a congenital defect. Immermann's theory of congenital weakness of the blood forming organs can be eliminated for the same reason as Virchow's theory. v. Bunge attributed the condition to a disturbance in the iron metabolism. Zander regards chlorosis as due to a disturbance of the absorption of iron. Gastroptosis, chronic constipation, the wearing of tight corsets, etc., all have had their day. von Noorden attributed the disease to a disturbance of the ovaries. The ovaries, according to von Noorden, exert a stimulating influence upon the blood building organs. Loss or weakness of the internal secretion of the ovaries leads to chlorosis. Grawitz considered chlorosis as a neurosis. Morowitz does not believe that anemia is an essential factor of the disease, but merely a part of the general syndrome, and thinks that iron acts through its beneficial effect upon the cause of the disease rather than by its action upon the blood per se. Morowitz believes that the disease is best explained by assuming the disturbance of a number of glands of internal secretion. This is a very alluring theory and certainly has many factors in its favor, such as its resemblance to hyperthyroidism, Addison's disease, and ovarian disturbances; however, it is not sufficient. No pathology has even been found in any of the glands in cases going to necropsy from accidental death, and the complete and prompt recovery under iron therapy does not bear out this theory. Iron certainly has no effect on any of the internal secretory glands in other conditions in which they are known to be affected.

Frederich Müller calls attention to the similarity between chlorosis and mild hyperthyroidism.

As has been stated none of these theories, nor any combination of them, explains satisfactorily the nature of chlorosis and the manner of its supposed cure by iron medication.

It is my purpose in this paper to bring forward a theory as to the cause of chlorosis which I believe will explain its various manifestations, and also to put forward a suggestion as to the manner in which the anemia is produced, and also why iron is of value in this condition.

I believe that careful consideration of the symptom-complex of chlorosis would lead to an appreciation of the correctness of a part of Morowitz's claim that chlorosis is not a primary anemia and that the symptoms are not due to the anemia itself. This is borne out by many facts. Perhaps the most important might be considered the fact that many authentic cases of chlorosis are on record by Morowitz, Laache, Naegeli, Grawitz, and others, having all the symptoms of chlorosis, except that the blood findings are normal, or almost so.

A. F. Byfield[1] describes a typical case of chlorosis in which the blood examination showed 90 per cent. Hb. (Sahli corrected); red blood cells 4,600,000; very slight poikilocytosis and anisocytosis. The symptoms complained of in this case, very thoroughly described by Byfield, are chiefly: Drowsiness and tendency to sleep the greater part of the morning, despite a good night's rest; feels better towards noon; frequent headaches; palpitation and slight edema; presence of cervical glands on both sides; temperature of 99.2° in the afternoon; blood pressure 95 65; presence of a slightly enlarged thyroid gland. These symptoms are all typical and characteristic of the type of condition present in a certain type of low grade infection in the tonsils, which I described recently.[2] In ruling out the chronic latent infection, Byfield states, "tonsils, teeth, etc., seem entirely normal." The presence of cervical glands in this case must be explained. Are they not due to infection from the tonsils, extending along the lymphatics to the glands? Formerly,

before the days of the Wassermann test, we were taught to put great reliance upon one or two glands in the posterior triangle of the neck in the diagnosis of syphilis. Why shall we lightly pass over a chain of glands in the anterior triangle? They probably indicate a source of infection that should be investigated.

The fact that the disease occurs in all classes of society, without regard to hygiene or mode of living, is suggestive. The infections are present in all classes. Osler's mention of the occurrence of the disease in Irish immigrant girls shortly after arrival at Montreal, suggests that a change of climate may result in activating latent infection in the tonsils, and the development of a symptom-complex called chlorosis. The drowsy, heavy headed feeling in the morning can scarcely be due to anemia, especially in the types showing a very mild blood change. I have seen this particular picture clear up often within twenty-four or forty-eight hours after the removal of the tonsils.

Hypotonicity of the cardiac muscle as a common condition in chlorosis has also been described in cases showing no blood changes, and is also mentioned in Byfield's case. Is it not more reasonable to explain this as due directly to a toxin acting upon the heart muscle? Low blood pressure, which is usually present, can be explained by the action of this toxin elaborated within the tonsil tissue on the adrenal gland. This gland, we know, is readily affected by infections, notably that of influenza, tuberculosis, and dipththeria. Vasomotor disturbances are not frequently noted as due to anemia, but are found in infections and toxemia.

At the meeting of the Ohio State Medical Society, held in Toledo in June, 1920, Dr. Crile mentioned the fact that he had developed an instrument for measuring the temperature of various organs *in situ*. He has found that the temperature of the brain is directly affected by adrenalin chloride injected into the blood stream. It may be possible to show a decrease of cerebral temperature in these cases if the adrenal gland is involved.

The albuminuria common in chlorosis cannot be explained by the anemia, especially when mild or not present. Severe grades of anemia may cause albuminuria by changes in the renal epithelium, yet we not infrequently see cases of pernicious anemia showing no albuminuria. Huebner examined at autopsy a kidney from a case of chlorosis dying from other causes, and found it to be normal. I have shown[3] that albuminuria is very common in cases showing tonsil infection, and that the albuminuria clears up very promptly upon removal of the tonsils, providing, of course, no other organic renal changes are present.

Osler mentions the occurrence of thrombosis, particularly in the femoral veins, as occurring in chlorosis. I have seen one such case. I believe that infection would be a more logical explanation for this thrombosis than anemia. The case which I saw, in a girl of fifteen, had infected tonsils, with a clinical picture of chlorosis and thrombosis, both femoral veins and many of the tributaries were involved. While in the hospital she developed a subacute attack of tonsillitis. Her tonsils were removed with complete recovery from the clinical picture of chlorosis. The presence of a subfebrile temperature in many of these cases is suggestive of a focus of infection.

The suggestion that chlorosis resembles hyperthyroidism in view of our present-day knowledge of the part played by infections in this condition is also suggestive. Simple enlargement of the thyroid gland is not an infrequent accompaniment of tonsil infection. The association between chlorosis and thyroid enlargement was brought out in a paper on "The Goitre of Puberty" published in 1915.[3] At this time the factor of tonsil infection was not appreciated. However, this triad of tonsil infection, enlarged thyroid, and chlorosis is so common that once the attention of the physician is called to the fact, he cannot help but notice it. Summing up the symptomatology of chlorosis, a low grade toxemia from a focus of infection somewhere in the body will more logically account for the clinical picture than will primary anemia. Indeed, the anemia itself is merely an expression of the toxemia, and is not infrequently met with in adults under toxic conditions.

Iron has always been considered a specific in the treatment of chlorosis. The manner of its action has not been definitely settled. Its mode of action is thought to be by stimulation of the bone marrow, and in supplying a sufficient amount of iron for the hemoglobin required by the red blood cells. The average body needs to maintain a normal iron equilibrium of from 5 to 10 mgm. per day. The normal diet contains more than sufficient iron for the bodily needs of the individual. Yet the excess of iron in the food is not sufficient to prevent chlorosis. There is no evidence of blood destruction in chlorosis. This, together with the plentiful intake of iron, has made it difficult to determine how and why the anemia results.

The suggestion offered here will explain both the method of production of anemia and its relief. The fact should be mentioned at this point, a fact well worth observing, that cases of chlorosis put upon iron in sufficiently large doses will show a subjective improvement within a few days. This improvement is manifest long before there is suffi cient improvement in the blood picture to attribute it to a decrease of the anemia. This fact I have noted time and again. It has therefore led me to believe that the symptoms of chlorosis are produced not by the anemia, but by some other factor, and I believe it is due to the toxins sent into the circulation from a focus of infection. This focus of infection is uniformly located in the tonsils in cases of chlorosis. This toxin is probably an endotoxin, or, if we accept Vaughan's theory, a bacterial protein. According to Gray[4] these are identical.

According to Vaughan these bacterial proteins are not specific and do not produce an immunity. The symptomatology depends upon their affinity for certain organs in the body, rather than upon their specific character. This is probably true here, as will be brought out later, and probably accounts for the differences in the clinical picture of so-called chlorosis in the girl, and the picture present in boys and adults suffering from the same type of infection. In attempting to explain the value of iron, we can assume that the iron has a particular affinity for this bacterial protein and forms a combination with it, possibly in the nature of an albuminate.

This combination "fixes" the toxin, rendering it inert. Assuming that this does happen, we can account for the anemia as follows: The iron taken in the food immediately after being absorbed into the blood, forms this combination with the free toxins, and is therefore not available for conversion into hemoglobin. If the individual is not getting unusually large amounts of iron in the food, anemia will result after the iron stored up in the liver has been used up. When iron is given for the cure of chlorosis it is given in large doses, so that there is sufficient to "fix" the toxin and also a sufficient amount is left for use in the manufacture of hemoglobin, and perhaps some also for storage in the liver. In this way we can account for the prompt relief of the symptoms within a few days, because the toxin is neutralized as soon as it is liberated from the tonsils and thrown into the circulation. The patient, therefore, is not suffering from a toxemia and will feel well, even before her anemia is overcome.

This theory will also explain the relapses so common in chlorosis. In giving these large doses of iron we have a storage of iron in the liver, sufficient above the quantity needed for fixation of the toxin, sufficient to last a variable length of time after withdrawal of the medication. When this stored-up iron has been used we again develop a subjective and objective change of chlorosis, to be again relieved by the second course of therapy.

The question might well be asked as to why chlorosis, if it is due to a focus of infection in the tonsil, occurs only in girls. A number of reasons might be advanced to explain this fact. In the first place it might be stated that chlorosis in boys has been recorded by Formanoli, Ferrari, Byrom, Bramwell, and others.[5] Secondly, it is possible that the type of food in the two sexes is somewhat different, the boy getting a greater amount of iron daily because of a larger quantity of green vegetables in the diet, while the girls at this particular age are prone to indulge in candies and sweets, thus reducing the appetite for other foods. Third the boys at this age indulge in healthy sports, outdoor exercises to a greater extent than do the girls. Fourth, there is undoubtedly some difference in the sensitiveness to toxins between the girl and the boy. We know that girls and women are more susceptible to powerful drugs, such as morphine, than are boys and adults. Might not this same susceptibility be present to certain toxins? Fifth, a very important factor is the normal conditions associated with adolescence in the girl. There is certainly a greater strain upon the bodily function in the girl during adolescence. The development of the sexual organs; the call upon the thyroid in association with the development of the ovaries; the greater degree of constipation which is usually present in these girls, as a result of improper habits, backwardness in leaving class rooms for attention to the bowels, etc., all are great factors in putting extra strain upon the body, thus lowering its resistance to infection, and making it more difficult to overcome infection when present.

It might furthermore be said that cases of tonsil infection in boys between the ages of 14 and 20, associated with debility, low blood pressure, general fatigue, and headaches, without the blood changes and greenish yellow color of chlorosis, are not at all uncommon. It is probably more a question of degree between the boy and the girl than it is a question of chlorosis being exclusively a disease of girlhood.

Indeed I might say that it has been my experience on questioning adult females who have been suffering from tonsil infections of the type described in the article referred to,[3] to obtain invariably a history of debility, languidness, variable appetite and poor general health during adolescence, suggesting that all these patients had chlorosis at this time, and later continued to suffer from the effects of toxemia, not classified as chlorosis.

Turley,[6] in studying the bacteriology of tonsils removed at operation, found in thirty-six cases the following bacteria: Gram-positive bacilli in seventeen cases; Gram-negative in nineteen; influenza bacillus in one; large *Staphylococcus albus* in six cases; medium-sized staphyloccus in twenty-six cases; small staphylococcus in four; *Staphylococcus aureus* in three cases; only one case showed no staphylococci; diplococcus in one case; pneumococcus in three cases; no streptococcus was found. These findings correspond to the bacteria ordinarily found in tonsils when cultures are made for the purpose of making autogenous vaccines for treatment. As these tonsils studied by Turley were taken from patients from early childhood to advanced life, they probably include a number of cases between the ages of 14 and 20, the age of chlorosis, and might be taken as representative of the type of bacteria ordinarily found within the tonsils at this age. A further study of the bacteriology in cases of chlorosis would probably reveal nothing new. In any consideration of cases suffering from tonsil infection it must be borne in mind that infected tonsils are capable of producing changes in the body in one of two days; first, by reason of entrance of bacteria directly into the circulation with a production of such conditions as appendicitis, cholecystitis, gastric ulcer, endocarditis, etc., or secondly, by reason of the entrance of the toxins into the circulation.

Rosenow has shown that under certain conditions some bacteria have an affinity for different organs of the body at different times. The infection of a given organ by bacteria from a tonsil is in no sense a specific one. The same can be said for the toxins. Vaughan has shown that bacterial protein from various bacteria produces the same general symptomatology and special features of any given disease resulting from these bacteria are due to an affinity shown by the toxin for definite organs. The symptomatology of chlorosis can very readily be explained on the basis of a non-specific bacterial protein. Turley raises the question as to the greater susceptibility of the female to tonsil infections. In his series of thirty-six cases, twenty-three were females and only thirteen males. However, in my series of thirty-eight tonsillectomies from July 1, 1919, to August 15, 1920, twenty-one were females and seventeen males. This series includes cases suffering from all of the causes mentioned in Turley's paper, in addition to eight cases of chlorosis.

The proof that the cause of chlorosis is a toxemia, the result of an infection within the faucial tonsils,

is easily had. If that is the only and sole cause, removal of these infected tonsils should bring about a prompt cure. This it does. The relief from the symptoms of chlorosis is very prompt. The subjective complaints disappear in less than a week. The improvement in the blood picture follows very shortly, and this without any medication whatsoever. Within the past year the tonsils were removed from eight cases of typical chlorosis. All of these cases showed a very prompt and decided improvement. Only one of these cases had any medication given after tonsillectomy. This case had a hemoglobin of 50 per cent., and I thought it advisable to give large doses of iron for a period of ten days to bring about a more rapid improvement in the blood picture. Each of these eight cases has been seen or heard from since and they have all made a complete recovery. I have not seen a case of chlorosis occur when the tonsils have been removed in childhood.

I have no desire at this time to enter into a discussion of whether tonsillectomy should be done in every case of chlorosis or whether iron medication should be used as heretofore. My present purpose is to call attention to the fact that chlorosis has a definite specific etiology, which is capable of demonstration and is therefore not a primary anemia.

Conclusions.—1. Chlorosis is not a primary anemia, but is due to a non-specific toxemia.

2. This toxemia is a result of a focus of infection in the tonsils.

3. Iron therapy acts beneficially by reason of its ability to combine with the toxin, producing a harmless organic compound; this not only preventing anemia, but improving the general condition of the patient, but not producing a permanent cure.

4. A permanent cure can be brought about only by removal of the tonsils and elimination of the focus of infection.

MOUNTAIN SICKNESS.

BY DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO, CALIF.

MOUNTAIN sickness is an asphyxia which occurs in the rare air of high altitudes. Not alone is the respired air thin and poor in oxygen, but its alveolar tension and barometric pressure are low, so that it is not pressed into the blood with the same force as at the sea level. Recently, on a trip to the high plateau of Bolivia and Peru, I had an experience with this distress, which is called by the Andean mountaineers, "soroche" or puna.

A striking peculiarity of this asphyxia is its stealthy onset. In ordinary asphyxia the distress follows immediately on the application of the cause, as in choking. In mountain sickness, however, the cause acts slowly, and the asphyxia comes on equally slowly. There is another cause, however, for the slow, stealthy onset of the asphyxia than the mere ascent into a rarer, lighter atmosphere and the consequent deprivation of oxygen, and this is the equally low alveolar tension and the increased facility for the escape of the carbon dioxide gas from the lungs. This can only be appreciated by considering more closely this phase of the physiology of breathing.

The Cause of the Incentive to Breathe and of the Distress on Being Smothered.—The incentive to breathe is not caused by a lack of oxygen, but by an increase in the acid H_2CO_3 ($CO_2 + H_2O$) in the blood. This acidity acts on the respiratory center in the medulla oblongata, stimulating the person to breathe. If an apparatus is constructed so as to absorb the CO_2 as it is exhaled in breathing, and at the same time prevents the replacement of the O_2, a person can, with such an apparatus, be smothered without any distress.

In going up a mountain the CO_2 gas escapes with greater and greater facility into the atmosphere which is becoming thinner and lighter. This is still more facilitated if the air is very dry, and the rush of water vapor out of the lungs is correspondingly great. And at this point there comes in the peculiar solubility of CO_2 gas in water.

As an instance of the solubility of CO_2 gas in water take the following: Leaves (cellulose $C_xH_xO_x$) in the bottom of a creek decompose, forming about equal parts of marsh gas (CH_4) and carbon dioxide. If these leaves are stirred up with a stick, bubbles will arise, and if these bubbles are caught they will be found to consist of marsh gas only. The CO_2 does not form bubbles, because it is so soluble that it is dissolved and floats away in the stream.

In the watery vapor leaving the lungs, therefore, the CO_2 gas finds a ready vehicle for escape. If the air is dry, the watery vapor with its carbon dioxide gas leaves the lungs quickly; if the air is rare and light, it also leaves quickly; and if the atmosphere is both dry and rare, it leaves very quickly. In ascending the western slope of the Andes all three of these conditions are combined. One ascends very rapidly to a great height, nearly 13,000 feet, in a few hours, where the air is very light and poor in oxygen, and as it never rains on this part of the South American coast and the country is a desert, the air is also very dry.

The elimination of the carbon dioxide gas from the blood under these circumstances is very rapid, and not enough accumulates to stimulate the respiration to the increased rapidity and depth required to enable it to meet the deficiency caused by the rare air, poor in oxygen. This deficiency in oxygen, therefore, grows more and more marked and, up to a certain point, without any warning whatever, till suddenly, usually on making some movement, the deficiency passes the point of tolerance and a most distressing choking sensation, with the feeling of impending death, is experienced.

We had left Antofogasta the previous evening, and all three of the party were in excellent health. We had thought of staying at a mine about 8,000 feet up to see one of the largest copper mines of the world and to adjust ourselves more gradually to the altitudes. Everything seemed so favorable, how-

ever, that we went forward, and we attained the high tableland without incident. I had left the compartment and had lingered perhaps longer than I realized talking to a passenger in another car. On my return one of our party was suffering severely from mountain sickness. The picture presented was most alarming. The cutaneous surface about the mouth, including the red of the lips and the outer surface of the eyelids, was a deep violet. The face was mottled red, and the eyes were lacrymose and injected. The whole attitude was one of keen distress, and the throat was gulping for air.

Each passenger had his favorite remedy. Aspirin was offered, not because it would be of any use, but because it was a medicine they had. Ammonia salts were also suggested, which would have further embarrassed an already embarrassed respiratory system. The natural remedy would be artificial respiration, done with the least expenditure of energy on the part of the patient, so as to take advantage of what air there was, and to give rise to the least amount of CO_2 gas. Adjustments would also gradually take place if the patient was not too much interfered with. Of course, the great remedy is, like that for seasickness, to return the patient to his natural habitat—in the one case to remove him to a lower level, and in the other, to land him on terra firma. This remedy, however, is not always feasible. In the present instance, by remaining on the train, we dropped to a slightly lower level, and we interrupted our journey at the nearest considerable town, which happened to be Oruro.

The headache is sometimes terrific, confining the patient to bed for days, and this also was present in the case mentioned.

There is a great individuality in the symptoms, some people going to great heights without any trouble whatever, while some have a feeling of suspension of respiration for a number of seconds, and others have insomnia with a tormenting lucidity of mind. A dentist whom I met in La Paz said that for hours he lay awake, but tranquil. Others have oppression, a feeling of fatigue and vertigo, throbbing of the temples, and a sound of rushing blood in the ears. Nosebleed is very frequent.

I knew one man who lived in Oruro at 12,500 feet elevation for some time without any embarrassment till one day, on making a sudden exertion to catch a passing vehicle, he tumbled over, and had to be sent down to the sea immediately in order to save his life. He had overstrained his heart. And this man's experience is interesting in another way, for a very quick ascent and an equally quick descent, especially when unaccompanied by exertion, are not particularly noticed.

We crossed the Transandino Railway from Valparaiso to Buenos Aires without any inconvenience whatever. While at the altitude of over 10,000 feet I even took fairly vigorous exercise in order to warm up, and did not notice any respiratory or circulatory trouble. But when one ascends to a still greater height and remains at this elevation, as one does on the high Andean plateau, it is a different matter. Before adjustments can take place the organs become fatigued and their reserve is used up.

Individual susceptibility varies greatly, and there are some who quickly acquire a resistance, their blood, their chest, their heart, and their nervous system adjusting themselves to the new conditions. The adjustment of the blood consists, among other things, in an increase of the red blood corpuscles, and this physiological increase is sometimes taken advantage of as a curative measure in anemia. While some people can adjust themselves fairly quickly to high altitudes, others require a long time to attain comfort. Other patients continue to be sensitive to altitude, while some others again become comfortable after a long or short stay, but on going to the sea level and returning, go through all their old misery.

It is said that lack of appetite and unreasonable behavior are symptoms of mountain sickness. Any lack of appetite we experienced could be accounted for in other ways than in terms of altitude. It is said that the conduct of some people on Pike's Peak (14,100 ft.) was so unreasonable as to require the presence of a deputy sheriff, and Bayliss suggests that unreasonable people met with under ordinary circumstances may be really suffering from want of oxygen. In our group I did not note any more than the ordinary differences of opinion, and we did not have to call in a policeman to settle these.

Among the natives I did not note any symptoms of mountain sickness as evidenced by blue lips; their dark integument precludes it showing on their hands. Many Europeans, however, had distinctly blue lips and hands. In Oruro I met an acquaintance, a young man, who had recently arrived. On the way up he did not suffer from mountain sickness, although he had passed over an altitude of 12,900 feet, but when I met him in Oruro, a couple of days after arrival, his lips and fingers were blue and tremulous, and he spoke hurriedly and nervously. He was going to a dinner that night at which he would be up late and probably overeat, and he was to take the train early next morning. As mountain sickness is an asphyxia involving both the respiratory and the blood circulatory apparatus, any undue exertion or indulgence impinging upon either of these systems is to be avoided. I did not see this man again, but to my mind he was taking a very great risk.

As we have seen, the reason for the unobserved incidence of the asphyxic attack is the lack of notice given to the respiratory center by the carbonic acid in the blood. To prevent this, therefore, the will should act as a substitute, and every two or three minutes a few deep breaths should be taken. More than a very few it is inadvisable to take, because even at sea level, if one breathes deeply several times in quick succession, it will lower the quantity of CO_2 too rapidly, and will cause dizziness, and this lowering of the CO_2 would be nearly as great an evil as a paucity of O_2.

Oruro, the town at which we stopped to recover our atmospheric equilibrium, is a wretched place, a decayed mining town. It is situated in a brown, stony desert covered with sagebrush, which resembles that part of Nevada one crosses on the railway. There are the same rounded mountains—those nearby, brown, those farther away, blue. There are the same steep-cut, dry watercourses, and the same sharp shadows of the clouds moving slowly over the plain. There is also the same clear air, and the beautiful sunsets, with transparent blue skies and distant purple hills.

Near our hotel there was a small plaza, mean and ordinary looking, but one evening in passing

through it we found it lit up by the wonderful desert glow, which made it enchanting.

Llamas and mankind are the chief pack animals, then come asses and mules. There are very few horses, as all their forage has to be brought in from a distance. Llamas are very cheap, costing from two dollars and a half up to nine dollars, and their cost of maintenance is also very low. They are turned out on the desert to eat a small, almost unobservable plant. In fact, natives told me that they eat earth, which serves to indicate how very unobservable the plant is. They are also fed on barley, which grows, but rarely ripens, in this climate.

Fuel is scarce, poor, and very dear; it principally consists of bundles of twigs gathered from the sagebrush on the desert. A bundle, an armful, costs about twenty cents. Llama dung is also employed. It struck me that a cheap llama would make a cheaper, better fuel than either sagebrush or the llama dung.

The climate, at this elevation, is cold. Although the spring was well advanced men came down to the dining room in their overcoats, but the Indians, for the most part, went barefoot, or wore leather sandals. They wore a warm woolen cap with ear lappets, and a good deal of clothing about the body, but how they endured the hardship of their bare feet on the cold earth was always a mystery to me. I have seen them in their bare feet at Crucero Alto, at the snow line, fourteen thousand six hundred feet altitude.

The human being is a bald tropical monkey, clothed with a coat of good protective hair only in certain situations. He has been enabled to live in inclement regions by means of the invention of clothing and habitations, and by his control of fire. Clothing and habitations, however, when not constantly renewed or kept clean, render him, by their very nature, one of the dirtiest animals, and the Indian of this high plateau is a striking example of this state of affairs.

The bread was a small brown loaf, sad in consistency and made of a coarse inferior flour. It was responsible for a continual looseness of the bowels from which I suffered while in this elevated country. The milk and butter were canned, and the coffee was unrecognizable as such. A dirty boy brought the "coffee" into the bedroom on a tray, which served as a beer advertisement, and was set down on a center table furnished with a dirty old table cover, but with no tablecloth. And this was the place that Fate had landed us to await adjustments to new conditions.

This is the natural habitat of the potato, and the dean of all the potatoes resides up here, but, as Father Zahm has remarked, a good mealy potato is not to be found throughout the length and breadth of the land. And Father Zahm is no complainer—he is one of those travelers to whom everything is delightful as long as he is on his way. I myself felt few effects from the altitude. Previous to starting out on the South American trip, my heart had been interrupting, giving rise intermittently to a slight, but disagreeable choking sensation in the throat. I was naturally interested to observe what it would do when I took it up nearly two and one-half miles high. It acted all right. On slight ascents it would accelerate its beat a little, as it should. And the steadiness acquired there has endured ever since. I suppose that my cardiac organ, itself so well supplied with nerves, reasoned as follows: "This fellow to whom I belong has a higher nervous system that is none too good as regards the secretion of what is called "judgment," or he would never have taken me to this place. I, therefore, shall have to brace up and meet the emergency myself." And it did.

One of the strangest features of our stay in Oruro was that, with all its dirt and discomfort, we enjoyed it. Our rooms were so situated that they looked right down into the principal plaza of the town, and we really were intimately in the midst of its ever shifting life. The people with their dirty strange costumes and shiftless ways were a constant source of interest and pleasure. The character of the people was so different from ourselves that they seemed actuated by entirely different motives, or not actuated at all. Take for instance the matter of peanuts. With us the peanut vendor is an alert little merchant with his wares done up in paper bags exactly measured and contained in a highly polished brass receptable, which keeps them piping hot, and which has attached to it a merry high-keyed steam whistle. In Oruro the vendor was a squaw, squatted on the sidewalk with the cold peanuts in a flat basket in front of her, and her only measure was her hand. She did nothing particularly to attract your attention, but if you wished some peanuts, she would stop a moment from chatting with her neighbor and take up a handful, more or less, and give you them for so many centavos. And this measure by the handful was only one instance of a striking lack of utensils seen throughout the whole high plateau.

Soroche, or mountain sickness, and its opposite, caused by too dense an atmosphere, and called "caisson disease," seem to have been more interesting to physiologists than to physicians. One of the best notes on mountain sickness I found is in that charming and highly instructive book, Bayliss' Physiology. Yandell Henderson has also studied this phase of respiration most interestingly, and many a time on the high plateau I wished I could have had fifteen minutes conversation with him.

After passing over Lake Titicaca and dropping down to Cuzco, which is about eight thousand feet, a decided amelioration was experienced. A still further drop in descending along the Urubamba River to Ollentaytambo brought still further relief to one of the party, who had, up till then, experienced a subconscious oppression in the chest unnoticed until so relieved.

It was not, however, till we reached Arequipa, on the western slope of the Andes that we became aware of the relief from the light air, the sombre skies, and the chilly atmosphere of the high tableland.

Besides its delightful climate and its cheerfully green irrigated fields, Arequipa looks clean, for it is built of an easily worked white pumice stone quarried in the vicinity. That it looks cleaner than it really is is quite another matter. The spotlessly clean English steamer that we embarked in shortly afterwards at Mollendo was an appreciated luxury, and when we reached the hotels on the Canal Zone we could hardly credit our senses.

A NEW PHARYNGEAL TUBE FOR ANESTHESIA IN ORAL AND HEAD SURGERY.*

By RAYMOND C. COBURN, M.D.,

NEW YORK.

PREVAILING methods of general anesthesia for the surgical removal of infected teeth are not entirely satisfactory. The method in most general use is ether by insufflation, with the tubes passed through the nares. It requires a deep anesthesia, however, to pass the tubes into the pharynx, whereas only a light anesthesia is needed to meet the surgical requirements.

Gas and oxygen administered with a nasal inhaler is also unsatisfactory for this work, as the inhaler prevents the surgical removal of the front upper teeth, and interferes with such removal of the side upper teeth. Besides, with this procedure, there is often considerable hemorrhage, so it is advisable to have the upper pharynx well packed with gauze, and this greatly interferes with respiration.

To overcome these objections I have devised a flexible and noncollapsible pharyngeal tube of sufficient size to maintain respiration unrestricted, and permit gas and oxygen to be administered, with the upper pharynx well packed and, at the same time, not interfere with the work of the surgeon.

The pharyngeal tube consists of a spiral wire

FIG. 1—Pharyngeal tube, uncovered, showing flexibility.

tube covered with a thin rubber tubing to make it air-tight. The spiral tube is very pliable, readily adapts itself to the shape of the throat, and remains patulous, even when tied in a knot (Fig. 1).

The distal end of the tube is attached to a rubber bag by means of an exhaling valve or nipple (Fig. 2). The tube is of such length that the bag is kept away from the patient's face.

I have been using a stand that has an ether attachment on it, but an ether dropper may be placed in the connection between the tube and bag.

Method of Use.—The patient is anesthetized with gas and oxygen, using the face inhaler. A little adjuvant anesthetic is added, if necessary. The inhaler is then removed, the mouth gag applied, the pharyngeal tube inserted over the base of the tongue, the pharynx well packed with gauze, preferably using one strip, and the administration of gas and oxygen (with an adjuvant anesthetic, if indicated) is continued through the flexible tube.

The tube is either fastened with a couple of strips of adhesive plaster to the side of the patient's face or held in place by the anesthetist. The breathing back and forth into the bag has a tendency to work the tube out of the pharynx, so attention must be paid to this feature. The tube is kept on the side of the oral cavity that is away from the surgical field.

This pharyngeal tube may be placed in position under a much lighter anesthesia than the nasal tubes in ether insufflation. Likewise, a much

FIG. 2—Pharyngeal tube covered and attached to bag.

lighter anesthesia may be maintained by it throughout the operation.

After use, the rubber tubing should be removed for cleaning and drying the spiral wire.

If the pharynx is well packed, a slight pressure will develop in the bag during insufflation. This may be relieved with either the pliable exhaling valve or the manometer.

I have used this method of administering gas and oxygen in operations lasting from a few minutes to two and a half hours, with satisfaction both to the surgeon at the time of the operation and to the patient after the operation.

Instead of using gas and oxyen, an insufflation or Junker apparatus may be substituted, either with or without the bag.

Another valuable method of using the tube is

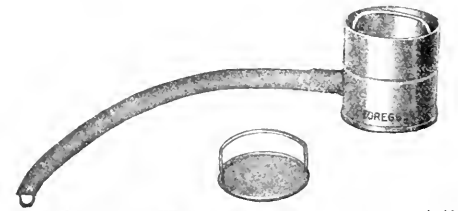

FIG. 3—Pharyngeal tube attached to ether cup; gauze shelf detached.

to connect the distal end to a cup (Fig. 3), which has a removable shelf for gauze. The anesthetic is dropped on this gauze, making it practically as open an administration as a face mask, with the additional advantage that the upper air passage is kept open, and the face and head are free for the surgical field.

I wish to acknowledge indebtedness to Dr. Henry A. Cotton, medical director, and Dr. John W. Draper, New York, visiting surgeon, N. J. State Hospital, Trenton, for the privileges extended in developing these methods of anesthesia.

HOTEL BRETTON HALL.

Spontaneous Spirochetosis in the Rabbit.—Levaditi, Marie and Isaiac have discovered a spontaneous spirochetosis in the rabbit which bears a notable resemblance to rabbit syphilis. Lesions of the nose and genitals were found to be due to a spirochete closely resembling the *Treponema pallidum*. Such lesions appeared to be papillomatous. Monkeys were found to be immune to attempts at inoculation with the newly discovered organism, and Levaditi and another also inoculated themselves with the same negative results. —*La Presse Médicale.*

SUPRAPUBIC CYSTOTOMY RING.

By EDGAR G. BALLENGER, M.D.,

PROFESSOR GENITOURINARY DISEASES, ATLANTA MEDICAL SCHOOL, MEDICAL DEPARTMENT, EMORY UNIVERSITY.

AND

OMAR F. ELDER, M.D.,

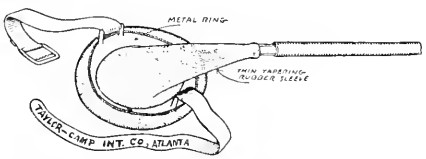
ATLANTA, GA.

ASSOCIATE PROFESSOR GENITOURINARY DISEASES, ATLANTA MEDICAL SCHOOL, MEDICAL DEPARTMENT, EMORY UNIVERSITY.

AFTER suprapubic cystotomy there is always a time when it is necessary to remove the tube which has been provided for the passage of urine, except when there is an inoperable malignant growth of the prostate and it is desirable to maintain permanent drainage through a tube.

There is consequently a period during the convalescence after suprapubic bladder operations when it is difficult to collect the urine and carry it to a bottle at the bedside. There are obvious disadvantages in employing a retention catheter, mainly for three reasons: (1) On account of the urethral irritation. (2) Because the urine frequently will not flow through it, but persists in passing out through the partly healed incision. (3) The patient cannot get around in a rolling chair with comfort with the urethral catheter in place.

After many years of using various devices we have adopted a very simple plan which has many advantages over the previous methods we em-



ployed. It consists of a large nickel-plated ring with two elevated connections for a webbing band similar to that used for trusses. These connections are sufficiently elevated to give the necessary downward pressure when buckled in place. A thin rubber sleeve is placed around the ring, as shown in the illustration, and connected at the other end to a rubber tube. This sleeve is of the thickness of an ordinary rubber glove.

After the removal of the suprapubic tube, the skin is covered with sterile vaseline and the device, which has been sterilized by boiling, is placed over the incision and buckled tight enough to hold the ring and rubber sleeve close to the skin around the incision. Within two or three hours it may be loosened or tightened, as required.

The tube is carried to the bottom of a bottle containing an antiseptic solution. As the tube fills with urine, the hydrostatic suction causes the thin rubber sleeve to collapse and stick close to the skin, leaving little or no space for residual urine. If desired, Dakins solution may be injected into the sleeve and the tube clamped so as to cause it to be retained in contact with the incision for a half hour or longer. This treatment is easily administered every two or three hours.

The urine will not leak around the rim unless the patient is very thin or lies on his side. He may sit up with comfort, and by this means we are able to get our patients out of the bed after prostatectomy earlier than formerly. Furthermore, being so simple to employ, the patient or some member of the family can fix it in place and adjust it, and the patient can leave the hospital earlier without having the discomfort of a wet bed. It is also easy for an interne, orderly, or nurse to place it in position and for the patient to loosen or tighten the band, as required.

The entire appliance can be boiled to sterilize, and the rubber sleeve may be renewed at small cost. It is made in several sizes, and with shoulders of different heights for the bands in order to obtain the downward pressure necessary for thin patients. The ring should be large enough not to press on the incision, and the appliance should be removed every few days and the incision and skin surface around it bathed with an antiseptic solution and covered with vaseline.

While this device somewhat resembles the conventional colostomy cup, it differs from it in several important respects; namely, it is more durable and may be boiled without injury, it is larger in size and may be applied without pressing on either end of the incision, and it is much less expensive.

The ring with a heavy rubber glove affords a satisfactory colostomy cup. The glove is thus substituted for the much more expensive bag supplied with the colostomy outfits.

HEALEY BUILDING.

Medicolegal Notes.

Procedure for Appointment of County Health Officers in New Mexico.—The New Mexico Supreme Court holds that the approval of the State Department of Health is a prerequisite to invest the nominee for county health officer named by the board of county commissioners of a county with authority, and without such approval there can be no such officer qualified to act. The disapproval by the State department of the nominee and the failure, neglect, or refusal to nominate one who is approved by the State Department of Health constitutes a failure, neglect, and refusal of the local health authorities to do the work which chapter 85, Laws 1919, designates shall be done by said State department, and authorizes the State department to perform such work at the expense of the county.—State Department of Health v. San Miguel County (N. Mex.), 195 Pac. 805.

Limitation of Actions—Tort Action for Malpractice Subject to Two Years' Statutory Limitation.—The Kansas Supreme Court holds that an action for malpractice in which it is in substance alleged that the defendant, in disregard of his obligations as a surgeon, performed an operation upon the plaintiff in a negligent manner, and not in accordance with the custom and practice followed by good, reputable, and ordinarily prudent surgeons, with a result that she suffered great pain and injury, for which she asked damages, is one arising on tort, and not on contract, and the Kansas statutory limitation of two years applies to such action.—Ericson v. Charles (Kan.), 194 Pac. 652.

Effect of Colorado State Board of Examiners' Decision as to License to Practise.—The Colorado Supreme Court holds that where the statute under which an applicant applied for a license "to practise chiropractic" made the State Board of Medical Examiners a tribunal to determine whether or not he came within the provisions of the law, and the applicant has been allowed a hearing upon the matters involved, and the determination of the question presented to the board was within its jurisdiction, the board's decision denying the application cannot be disturbed by the supreme court on writ of certiorari.—State Board v. Boulls (Colo.), 195 Pac. 325.

THE RADIOGRAPHIC STUDY OF THE RENAL ARTERIAL CIRCULATION.

FROM recent work done on this subject by Gérard, Castiaux and others it would appear that there is never a complete suprapyramidal arterial arch; the peripyramidal arteries converge toward each other at the base of the pyramids but never anastomose. The peripyramidal arteries divide individually at the borders of the cortical and medullary substances at a more or less considerable distance from the surface of the kidney, giving off innumerable lobular arteries — radiated arteries — exclusively destined for the cortex; they are parallel, directed toward the capsule, and are terminal and quite independent. Therefore, each pyramidal artery is autonomous and terminal, apparently destined for a lobe of the kidney. The arteries of the kidney are grouped in autonomous terminal territories. Each of the branches of the renal artery becomes subdivided, but each arterial territory of the kidney is derived from a branch of the renal artery. The territories are to be divided into two different areas:

(1) An upper, middle and lower territory following horizontal planes, as found in the pig, cow, sheep and man; (2) in front of and behind a frontal plane passing almost exactly around the circumference of the kidney, in anterior and posterior territories, as in the dog, rabbit, and polecat. This division is schematic, since some territories belong to both the vertical and horizontal planes. There is no radiographic evidence of the existence of straight arteries in the medullary substance and the vessels described as such must be connected with the very visibly distinct veins which form the dark rays of the Malpighian pyramids.

Castiaux has frequently found rather numerous fine collaterals arising directly from the peripyramidal arteries over the entire extent of the lateral aspects of the pyramids and which are directly distributed in the medullary substance of the latter, as well as to Bertin's columns. The capsulofatty arterial circulation, described by the classical writers, does not exist. It is present only in areas where fat is abundant. The vessels are few and are derived from either the perforating arteries or branches of the renals themselves. Fine arteries are found in the fat of the hilum and sinus arranged in a plexus which likewise furnishes the *vasa vasorum* of the vascular pedicle. Finally, the ureteral arteries, usually derived from the inferior branch of the renal, sometimes anastomosed in a plexus around the renal pelvis and ureter, are derived from three very different sources: (1) From the renal artery, near the hilum; (2) in the hilum, and (3) in the renal parenchyma, in which latter case they are given off from a peripyramidal artery.

This description will suffice to indicate the modern views of the arterial circulation in some mammiferous animals and man. The renal artery divides into two, three, or four branches either near the aorta—in which case it is premature—or near the hilum or even in the sinus—a tardy division. These branches in turn divide on the one hand in front of the vein and renal pelvis to irrigate the anterior frontal segment of the kidney; on the other, behind the renal pelvis—there is always a retropyelic artery—to supply entirely or in part the posterior frontal segment of the kidney. Each of the branches is destined for a portion of the organ. It gives off a certain number of ramifications which, by division in the sinus or Bertin's column, give rise to the peripyramidal or lobar arteries. The lobar arteries travel through Bertin's column between two pyramids and furnish both collaterals and terminals. The collaterals—which do not exist in all preparations examined—are represented by frail branches derived from the lobar artery in its course through Bertin's column, which branches to the right and left in a more or less oblique direction into the medullary substance; they are destined for the pyramids.

At the base of the pyramids the lobar arteries bend toward each other without anastomosing and furnish branches which in turn do not anastomose and it appears very probable that a *complete* superpyramidal arterial arch never exists. The lobar artery or its branches give off innumerable branches. These are the interlobular radiated arteries which go directly toward the periphery of the kidney and are destined exclusively for the cortex. They are terminal vessels and give off the afferent glomerular branches. Some of the radiated arteries directly perforate the renal capsule and plunge into the perirenal fat. The existence of straight arteries appears very doubtful; the arterial circulation of the pyramids is perfectly assured by the medullary collaterals which do not appear to have been described until recently by Castiaux.

Briefly, the arterial renal circulation seems to be effected very simply, each of the last branches of the divisions of the renal artery becoming an autonomous territorial vessel. It is the lobar arteries that give off the collaterals—medullary arteries, and the terminals—cortical radiated arteries.

VENTILATION AND EFFICIENCY.

So far as the practice of medicine is concerned, signs seem to signify that its future course is largely in the direction of preventive medicine, and while there will always be plenty of scope for the practice of curative and remedial medicine, the energies of the profession will be concentrated more and more on the preventive side. Also, treatment will be directed rather to preventing disease from going beyond its early stages than to treating and endeavoring to cure disease when developed. In order to be able to do this properly, one must learn how to detect the early symptoms of disease and so to treat them that their development may be arrested. Prompt diagnosis is the crux of this problem, and Sir James Mackenzie with great foresight, is demonstrating at St. Andrews, Scotland, how this may be brought about. In the field of preventive medicine, wide as it is, no part is so important as that of industrial medicine.

The fact that the efficiency of the worker, and therefore the prosperity of a country, greatly depends on the conditions under which he works, is beginning to be thoroughly recognized in every civilized country. Factories and workshops are being reconstructed on sound sanitary and hygienic principles and in all progressive industrial establishments able and adequate medical services have been established. Of the hygienic measures calculated to maintain the health of the worker in factory and workshop at a high standard good ventilation is one of the most essential. A constant supply of fresh air is necessary for the conservation of sound health. Where there is not such a supply workers are certain to suffer in fitness. An interesting review of certain work done along this line appears in the June number of *Tubercle*. Dr. Leonard Hill is one of the foremost authorities of the world on ventilation, and one of his chief contributions to atmospheric science is the devising of the kata thermometer. By this instrument the physiological value of any atmosphere can be estimated. It is pointed out that for the moment this instrument appears to be finding favor with those interested in industrial hygiene rather than with physicians. The review first deals with Report No. 11, 1921, of the British Industrial Fatigue Research Board written by Messrs. W. Hambly and I. Bedford. The report discusses observations made with the kata thermometer in boot and shoe factories, workers in which have been shown to suffer unduly from pulmonary tuberculosis. The position is accepted that the air in a well ventilated room should be cool rather than hot, dry rather than damp, diverse in its temperature in different places and at different times, moving rather than still. The authors note the conditions they found, suggest what standard of ventilation they consider should be maintained, and show how such a standard may be attained. They direct attention to the fact that the standard should vary for different types of work and suggest a mean temperature of 66° F., with an air movement of 8 feet per minute for sedentary work requiring delicate finger movement; a mean temperature of 62.5° F. with an air movement of 10 feet per minute for work of medium activity; and a temperature of 57° F. with an air movement of 10 feet per minute for heavy physical work. Emphasis is laid on the value of check temperatures as a guide to demands which are being made on the heat regulating system of the body and on the need, in order to minimize fatigue, of avoiding visible sweating. Daily and seasonal variations in ventilation were found, the evening being worse than the morning, and the winter than the summer. Ventilation was discovered to be better maintained in many story factories, probably due to greater exposure to windage, than in single story ones. Generally speaking, no effort was found to be made to adapt temperature and air movement to the nature of the occupation, and conditions unsatisfactory as measured by recommended standards were found prevalent.

The second report discussed emanates from the Rand gold fields.* These workers, using the kata thermometer for examining the air under working conditions in the mines, set themselves the task of measuring the effect of atmospheric conditions upon output and fatigue. Efficiency taken at 100 with a cooling power of 6, measured by the dry kata thermometer, was found to fall to 50 when the cooling power fell to 1. As a result of observations made throughout a section of the mine, the authors concluded that 21 per cent. of the output was being lost through inadequate cooling of the air. By the simple device of stirring up air in oppressive conditions so that a current blew over the operators, 46 per cent. of increase of output was obtained on one day and 32 per cent. on another.

These reports, the second one in particular, demonstrate the closeness of the relationship between ventilation and efficiency and thus between good ventilation and national prosperity. They show convincingly that work cannot be done, as it ought to be done, unless plenty of fresh air is supplied to the workmen. Moreover, good ventilation, which signifies in the main movement of air, is only one, albeit a most important one, of the essentials of good work. Industrial sanitation and hygiene well carried out in all their aspects should go far to dispel the unrest now pervading all ranks of society. Unless the worker is prosperous and contented everything will go awry and eventually chaos will result. Industrial medicine has a great part to play in the settlement of the world.

FOSSIL MEN.

Two fossilized human skulls from Java, recently described to the Royal Society of Amsterdam by their discoverer, Dr. Eugene Dubois, have thrown new light on the history of the human race, or perhaps we should say human races, for several extinct human types are now known, as different from existing black, yellow, or white man as the chim-

*"A Contribution to the Study of the Influence of Mine Atmospheric Conditions on Fatigue." A. J. Orenstein and H. J. Ireland, *Journal of the South African Institution of Engineers*, March, 1921.

panzee is from the gorilla. Dr. Dubois himself discovered the most notable of these, also in the rocks of Java, a low-browed creature, definitely human, and yet so apelike that the designation Pithecanthropus erectus, the "erect ape-man," was coined for it. He found the portions of the skull and thigh bone, on which all our knowledge is based, in the early nineties, but had also brought back two larger and more complete skulls discovered some years previously.

In 1918, Dr. S. A. Smith, of the University of Sidney, published an account of a fossil human skull from Pleistocene beds in Queensland, showing that man was present in Australia in the remote age when Great Britain was covered with ice. This skull had anatomical features closely similar to those of existing Australian natives, but it was more robust, with a larger brain-cavity and extremely massive jaws. Dr. Dubois, reading this description, remembered his Java skulls, took them from their cabinet, and examined them with care. They likewise are of the Australoid type, robust, large-brained, and with massive maxillaries. They have been associated by a recent English writer with a fossil skull found in the Transvaal and also with a famous skull found some seven years ago at Piltsdown, in Sussex, England. These, too, had exceptionally large brain cases and massive maxillaries. The brain of the former might have been larger than that of Bismarck, and the jaw of the latter was so remarkable that a certain American anatomist "jumped the English claim," and named from it a new species of fossil chimpanzee.

The skulls from Australia, Java, and South Africa have now supplied evidence on which we can dismiss the strange notion that a Sussex gravel-pit should have contained a unique human skull without an inferior maxilla and a unique chimpanzee lower jaw without a skull. But they seem to establish the existence of a widespread primitive human type possessing an ape-like lower jaw and a brain at least as large as that of modern man. Metchnikoff once suggested that man had arisen from the apes as a sudden large-brained "sport"; but why may the ape not just as well be a descendant of idiot man? There are other qualities in brains than those dependent merely on size, but mental ability is looked upon as the leading factor in the differentiation of man from animals.

The Pleistocene large-brained men may also remind us of many other discoveries establishing the existence of civilizations long antecedent to those of which we have historical débris. However proudly we may trace the development of existing institutions, we may do well to remember that they have followed other civilizations, as great or greater and also possibly as confident of their own superiority and permanence.

Quinidine in Complete Arrhythmia.

Quinine at one time had a reputation as a cardiac poison, but it has also been used not infrequently for its sedative effect in angina pectoris and tachycardia, especially in exophthalmic goiter. The use of quinidine as a cardiac goes back only to Wenckebach, in 1914, who obtained favorable results in arrhythmia perpetua. For some years nothing more was heard of this use of the drug, but in 1918 Frey showed that it was superior as a cardiac to quinine and cinchonine and that in about half the cases it could control fibrillation. Still better results were obtained by Bergmann, who showed that it always helped fibrillation and abolished it in over half the cases. This was confirmed by Wybouw, who published convincing electrocardiograms. It cannot replace digitalis but enables us to spare that drug by alternating the two. The sulphate appears to be the better salt but the optimum dose has not yet been determined. Half a gram three times daily appears to be the running dose suitable to these cases, but others have chosen to begin with a small dose and push it to tolerance. In certain cases, evidently those which are refractory, the ordinary dose may be increased, but there is nothing mentioned higher than two grams (30 grains) in 24 hours. There is no rule concerning the length of time of exhibition but from 3 to 8 days appears to be sufficient. Cheinisse, from whose article in *La Presse Médicale* of May 28, 1921, xxix, 43, we obtain these data, cites one unfavorable report, by Klewitz, who obtained completely negative results with both quinidine and quinine. It is certainly advisable to test this drug in arrhythmias.

News of the Week.

Decline in the Death Rate.—Statistics compiled by the Metropolitan Life Insurance Company show a marked decline in the death rate during the last six months. The rate for the half year is 23 per cent. below that for the first half of 1920. The most marked declines are in influenza, pneumonia, tuberculosis, and organic heart disease. The death rate for influenza for the first six months of this year was about one-ninth of that for the first half of 1920; likewise the mortality from pneumonia for the first half of 1921 was about one-half that for the corresponding period of last year. These decreases, together with drops of 19 per cent. in the tuberculosis rate and 9 per cent. in that for cardiac diseases, are the chief elements responsible for the remarkably low mortality rate. Cerebral hemorrhage and Bright's disease have also registered considerable declines. Measles and whooping cough were slightly lower than for last year.

General Hospitals and Tuberculosis Patients.—The United States Public Health Service has issued a bulletin expressing the belief that the opening of wards in general hospitals for tuberculosis patients, as recommended by the American Medical Association at its recent annual meeting in Boston, marks a distinct advance from the standpoint of prevention as well as of treatment. The treatment of tuberculosis in a general hospital has the advantage that the diagnosis will not be made public, and at the same time all precautions will be taken to avoid the infection of others. In support of this new policy it is argued that in many small cities two hospitals, one general and one for tuberculosis, can be run only at a loss, but if combined would pay operating expenses, especially as a combined hospi-

tal would draw many secret tuberculosis cases. Another advantage of the plan is that it would enable people in moderate circumstances to obtain preliminary treatment in their home towns, and such treatment would habituate the patient to the regimen essential to his cure and to the protection of others, and would enable him to go home and get well under home treatment. From the standpoint of the physician, his visits to the patient in the hospital would familiarize him with the treatment of tuberculosis and would enable him to recognize cases earlier. It would also train him in the supervision of home patients.

Welfare Committee of the Medical Society of New Jersey.—This committee, recently appointed by Dr. Henry B. Costill, president of the State Society, met in Trenton, June 29, 1921, and outlined a legislative campaign, which included a proposed measure to deal with the demands of the osteopaths to practise medicine and surgery by the setting up of a single standard of qualifications for all who would receive an unlimited license to practise. There is also the intention to seek an amendment to the workmen's compensation law, which would provide for what the physicians think would be a fair compensation for both the hospital and the physician in the care of persons injured in industry. It was decided to ask the State Board of Institutions and Agencies to place a physician on the board of managers of the various State institutions in which the care of the health of the inmates is a large factor. The committee also recommended that a physician be placed in an executive position on the State Rehabilitation Commission. The committee is composed of Dr. Wells P. Egleton, Newark; Dr. T. W. Harvey, Sr., Orange; Dr. D. C. English, New Brunswick; Dr. John McCoy and Dr. Donald Meyer, Jersey City; Dr. Frederick Quigley, Union Hill; Dr. S. J. Quinn, Elizabeth; Dr. W. A. Carrington, Atlantic City; Dr. H. L. Rose, Camden, and Dr. Fred H. Morrison, Newton.

Bronx Physicians Start a Medical Center.—Bronx physicians have established a medical center which will serve as a common meeting ground for physicians as well as laymen, where problems relating to medicine and of mutual interest to both will be given consideration. In order to keep the practitioner abreast of current advances in medicine the organizers of this center plan to conduct a continuation school for physicians where they may both give and receive instruction. This Academy of Medicine will also undertake special research work in all problems of benefit to the public health and welfare. For the public, lectures will be regularly delivered on topics of child welfare, preventive medicine, public health education, and first aid to the sick and injured. All these lectures will be previously revised and approved by groups of specialists. This new organization is to be known as the Bronx Physicians' Club and will comprise the members of various medical societies and those active in hospitals, dispensaries and the Health Department. The scientific activities, however, will be open to all physicians, whether members or nonmembers. To carry out these plans the Bronx Physicians' Club is seeking $500,000 with which to erect and maintain an edifice within easy access to the population it is to serve. In order to raise funds a bazaar will be held from October 8 to 15, 1921, at the Second Field Artillery Armory at 166th Street and Franklin Avenue, Bronx.

American Nurses' Memorial in Paris.—The new Florence Nightingale Training School for Nurses, established at Bagatelle, a suburb of Valence, was recently dedicated, at the laying of the cornerstone, to the 284 American nurses who gave their lives in the war. The new school was erected by the nurses of America through small individual subscriptions. Rear Admiral Thomas P. Magruder, American naval attaché in France, presided at the ceremony. The cornerstone was laid by Miss Helen Scott Hay of Savanna, Ill., chief nurse of the American Red Cross in Europe, in behalf of Miss Clara D. Noyes, president of the American Nurses' Association, and chairman of the Fund for the Memorial.

Nurses' Home for St. John's Hospital.—A contract has been awarded for the erection of a new three-story and basement fireproof building for the accommodation of seventy-five nurses connected with the training school of St. Johns' Hospital, Long Island City, N. Y.

New Jewish Memorial Hospital.—Plans have been completed for the Jewish Memorial Hospital to be erected at Dyckman Street, New York, overlooking the Hudson River. The new building will be dedicated to the memory of the Jewish soldiers, sailors and marines who died in the World War. The Magdalene Home, which now stands on the site, after extensive reconstruction, will be utilized as a part of the hospital, and this with the new building will afford accommodations for 165 patients. A dispensary will be conducted in connection with the hospital. It is estimated that the completed structure will cost $350,000.

Campaign for American Hospital at Neuilly.—Subscriptions for a new 100 bed addition to the American Hospital at Neuilly have totalled 1,045,800 francs during the first fortnight of the drive for funds. The fund committee will continue its efforts until 5,000,000 francs is obtained. Construction work will be begun at once without waiting for the completion of the fund.

Physicians and Nurses Needed in Alaska Medical Service.—The United States Bureau of Education is undertaking to do what it can to check the ravages of tuberculosis and other diseases among the native races of Alaska. For this work physicians and nurses of good educational qualifications, successful experience, upright character, and altruistic motives are desired. A physician in the Alaska Medical Service is required to supervise one of the small hospitals maintained by the Bureau of Education or, under the direction of the District Superintendent of Schools, to make tours of inspection of the schools in his district, furnishing medical relief to the inhabitants and endeavoring to maintain sanitary conditions in the homes and villages. The salaries paid to the physicians in the Alaska medical service range from $1,800 to $2,800 and those of the nurses from $800 to $1,400 per annum. The Bureau defrays traveling expenses. Persons desiring these positions are not required to pass an examination, but must make application on the form prescribed by the United States Bureau of Education.

Women Physicians Accused of Libel.—The for-

mer president of the Board of Trustees of the New York College and Hospital for Women has started a libel suit in Rockland County for $50,000 damages against four women physicians formerly interested in the institution, charging that the women libeled him in a report of the Alumni Association of the college to the American Institute of Homeopathy. In their reply the defendants reiterate the charges made in the report, namely, that the plaintiff and two colleagues managed the affairs of the institution so that the building became the property of a corporation of which they were trustees.

Doctors Reduce Fees.—The physicians of Conway, Ark., have put into effect an agreement which returns their charges to pre-war levels. For day visits within the city limits the charge is now $2 instead of $3, and for night visits inside the city the fee has been reduced from $4 to $3.

Italian Liner Brings Smallpox.—A sixteen-year-old boy developed smallpox on the voyage from Genoa on the Italian Liner *Giuseppe Verdi* which arrived at the Port of New York on July 13. The 935 steerage passengers were transferred to Hoffman's Island for vaccination.

Course of Training for Public Health Nurses.—The Bedford College for Women, University of London, announces a course for the training of public health nurses. The course has been established in order to seek out in all countries the nurses who by reason of intelligence and training may become leaders in the evolution of nursing ideals in their own country. These women will be trained to become pioneers in public health nursing, where that service is just being started. During the past year nineteen students from eighteen countries have taken a similar course under the auspices of the League of Red Cross Societies. These students will return to their countries as trained leaders and staunch advocates of more efficient public health nursing services.

The International Congress for Protection of Infants began its three days' sessions in Brussels on July 15 under the patronage of the King and Queen of Belgium. One of the features of the first session was a paper by Nathan Strauss, who described the way in which he had succeeded in introducing pasteurized milk into New York and the benefits that had accrued from its use.

Dr. G. A. Jordan has been appointed Hospital Commissioner of St. Louis, to succeed Dr. Cleveland H. Shutt, who resigned in April after sixteen years of service.

Dr. John C. Hupp has been appointed Health Officer of Elm Grove, W. Va., to succeed himself.

Dr. Alfred S. Burdick has been elected to fill the vacancy as president of The Abbott Laboratories of Chicago caused by the death of Dr. W. C. Abbott.

Dr. Edward T. Hull has removed his office to 304 West Seventy-eighth Street, New York City.

Medical Society Elections.—THE SOUTH DAKOTA SECTION OF THE AMERICAN COLLEGE OF SURGEONS, at its meeting held in Aberdeen, June 28, 1921, elected the following officers: *Chairman*, Dr. G. G. Cottam, Sioux Falls; *Secretary*, Dr. F. A. Spafford, Flandreau; *Counsellor*, Dr. F. L. Putnam, Sioux Falls.

THE ARKANSAS STATE MEDICAL SOCIETY, at its organization meeting held in Little Rock, June 10, 1921, elected the following officers: *President*, Dr. W. F. Smith, Little Rock; *Vice-President*, Dr. W. H. Toland, Nashville; *Secretary*, Dr. J. W. Walker, Fayetteville; *Treasurer*, Dr. J. T. Palmer, Pine Bluff.

THE COUNTY AND CITY HEALTH COMMISSIONERS OF SOUTHWESTERN OHIO, at their annual meeting held in Cincinnati, June 8, 1921, elected the following officers for the ensuing year: *President*, Dr. C. A. Neal, Hamilton County; *Secretary*, Dr. H. H. Panzing, Montgomery County.

Obituary Notes.—Dr. ALFRED D. SAWYER of Fort Fairfield, Me., died after a lingering illness, on June 20, at the age of sixty-six years. He was graduated from New York University Medical College in 1880. He was an ex-president of the Maine Medical Association and a member of the Maine House of Representatives in 1919-1920.

Dr. WILLIAM BROOKS SWASEY, a graduate of Bellevue Hospital Medical College in 1867, died of cerebral hemorrhage at his home in Cornish, Me., on June 2, at the age of seventy-eight years.

Dr. DE FOREST S. TIFFANY, a graduate of the State University of Iowa College of Homeopathy, died suddenly of heart disease at his home in Waterloo, Ia., on May 29, at the age of forty-nine years.

Dr. W. A. ORENDER, a practitioner under the registration law, died in Mansfield, Mo., on May 31, at the age of seventy-four years.

Dr. HARLOW H. WHITNEY of Northfield, Vt., died at his home in Enosburg Falls on May 20, at the age of forty-five years. He was a graduate of the University of Vermont College of Medicine in 1907, and formerly college physician at Norwich University.

Dr. JOSEPH MATTESON, a graduate of the Northwestern University Medical School in 1878, died at his home in Chicago on June 1, at the age of seventy-two years.

Dr. CHARLES A. STILLWAGEN of Pittsburgh died on June 4, after a long illness, at the age of fifty-five years. He was a graduate of Jefferson Medical College in 1892, and took post-graduate courses in Berlin and Vienna. He was a member of the surgical staffs of the Pittsburgh and Columbia hospitals, and a captain in the M.C., U.S.A., during the World War.

Correspondence.

TREATMENT OF FRACTURE OF THE NECK OF THE FEMUR.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—From a paper on fractures by Dr. Ethan H. Smith of San Francisco (MEDICAL RECORD, July 9) I quote as follows: "In fractures of the neck of the femur whenever the lower extremity is abducted, the adductor muscles serve as a fulcrum while the upper extremity of the femur adjoining the neck serves as the short arm of the lever, while the whole thigh and leg serve as the long arm. The adductor muscles pull not only inward, but upward. The fragments involved in the fracture are unnecessarily jammed and over-riding of the neck of the femur by the shaft is almost sure to follow. Shortening of an inch or more is the rule, rather

than the exception. It does not matter who the surgeon is, or whether he uses a Hawley table or not, the above mentioned holds good."

The abduction treatment, which the writer evidently has in mind, is applied under anesthesia and therefore during muscular relaxation. The "fulcrum" is not the adductor muscles, but the capsule of the joint. The position of complete abduction places the fragments in an end-to-end relation so that mutual pressure, the best assurance of security in this, as in other fractures, is provided. Exaggerated abduction would not cause "over-riding" but would have exactly the contrary effect.

It is interesting to note that Dr. Smith is apparently perfectly satisfied with the conventional traction and sandbag routine. In his experience this assures comfort, freedom from pneumonia, while "recovery with shortening scarcely to be demonstrated is the rule." In the practice of others treatment of this character has proved practically futile in so far as intracapsular fractures are concerned, and neither comfortable nor free from danger.

The abduction treatment which applies surgical principles, and which assures the demonstrable opportunity for functional repair, is designed in the interest of reform to supplant what has been termed the surgical ritual based "on the straight pull with the old-time weight and pulley." For this reason it seems proper to suggest that Dr. Smith's misapprehension of the mechanical principles on which the abduction method is based, and his consequent lack of experience in its proper application, manifestly lessen the value of his opinion on the subject.

ROYAL WHITMAN, M.D.

NEW YORK.

ALL OUT OF STEP WITH JIM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In a letter to the *New York Medical Journal*, published June 1, 1921, signed by Dr. Alfred C. Prentice, there are some observations concerning narcotic drug addiction with a reference to certain ideas voiced by me and many others, which he calls "plausible romance." In an article in the *Journal of the American Medical Association* of June 4, this same doctor offers a more extended discussion of the addiction matter from his particular point of view. In this article there is an inference to the effect that those differing with the doctor in opinion and giving voice to their ideas are propagandists or worse. Some of their statements, or his apparent idea of their statements, are feebly classed as "fallacies." It appears from this article that quite a considerable number of what have always been regarded as responsible publications have been guilty of printing things of which this Dr. Prentice does not approve, and which he consequently calls "fallacies."

In the list of journals appear *American Medicine*, *Illinois Medical Journal*, *American Journal of Clinical Medicine*, MEDICAL RECORD, *American Journal of Public Health*, Washington *Post*, Chicago *Tribune*, New York *Tribune*, *New York Times*, New York *World*, New York *American*, *Harvey's Weekly*, *New Republic*, *Metropolis*, "and others." By the way, "and others" is right. There might be added to the list given by the writer of the article a very considerable number of "others." In fact, a survey of the literature on narcotics and addiction reveals a very comprehensive list of conservative and reliable publications, medical and lay, which have at one time or another qualified for admission to the group mentioned in criticism by Prentice as publishing things with which he does not agree, in other words, "fallacies." There is also a rather impressive amount of material from legislative, judicial, administrative, committee, and other study and investigation which belongs to this collection of "fallacies."

In fact, there is so much of this sort of material that consideration of it in connection with some of the announcements of Prentice recalls a song that was popular a short time ago. According to the song, a proud and fond mother watching her son, a "rookie," parade with his regiment, made the startling and illuminating discovery that in the company of marchers to which her son belonged,

"They were all out of step but Jim."

A good deal of sympathy ought to be extended to Prentice because so many reliable and responsible publications and experienced workers are out of step with him. Finding it out must have been considerable of a shock. Perhaps it is inexplicable to him that all these publications and people can't get out of their minds the accumulated evidence on this subject, forget all that past experience has taught, and so get into step with him. Facts are stubborn things, and there are a lot of them now on record and known to a lot of people, like editors and judges and doctors and health workers and writers and legislators and administrators and others, all of whom are certainly *"out of step with Jim."*

Prentice's complaint against publications that print things that he doesn't like might be extended to other publications than those he names. Among these is an official report to the Medical Society of the State of New York, adopted at its last Annual Convention, which refers in rather specific detail to certain oppositions to the ideas Prentice is on record for sponsoring. This is the Report of the Committee on Legislation of the State Medical Society, to be found on page 209 of the June issue of the *New York State Medical Journal*. It received added endorsement by the election of the chairman of this committee to the Presidency of the Society. The report refers to the certain committees which were appointed in this narcotic matter, whose reports are "apparently written *ad hoc* by an interested group comprising not more than ten men in the medical profession and a couple of lawyers" with whose activities the committee on legislation is not in accord and whose representations do not, to say the least, represent a consensus of opinion of the medical profession. Of how many of these committees Prentice is a member and whether he is one of the "not more than ten men in the medical profession and a couple of lawyers" we do not know, but evidently this report from his own State medical society seems to be another thing that is "all out of step with Jim."

I wonder sometimes in reading some of these articles if those who write them are not getting just a little nervous about the facts. Criticising every-

body who is out of step, without giving any satisfactory foundation for the criticism is not always a sign of strength and assurance. There was a situation a good deal like the present one only a few years ago in which efforts were made to pass legislation and secure interpretation along much the same lines and "formularizations" that Prentice is interested in. The situation got so bad finally that there had to be an investigation by a joint committee of the legislature working for two years to get at the real truth. The testimony in the report of that committee, the Whitney Committee of New York State, seems to be another thing that is "all out of step with Jim."

Then there are the various discussions, hearings, etc., in the matter of the Cotillo Bill and the Fearon-Smith Bill, referred to as the "second Smith" bill in the Legislative Committee Report, among whose proponents was and apparently still is Prentice. The Cotillo Bill effort came during an early period in his interest and activity in the subject—indeed, so far as I can find out, when he was a "rookie" in narcotic activities. In opposition to this bill was an imposing array of men who had had real experience in the subject and who knew what they were talking about—judges, district attorneys, health authorities, doctors, legislators, and others, all of whom were very much "out of step with Jim."

It would be a little unfair to close this note without calling attention to at least one statement from Prentice which seems to the writer to be, in part at least, not debatable. In a recently published letter he says that he has never been engaged in the treatment of drug addicts in his practice, and further disclaims "any personal interest whatever in their treatment, institutional or otherwise, save only the common interest in the public welfare to be gained through a proper solution of the narcotic drug problem." As to how the carrying out of the ideas and policies which he seems to support have already affected and reacted upon and would still further affect and react upon "public welfare" is a matter upon which there is a lot of reliable testimony which is "all out of step with Jim."

It really seems rather too bad when men in the position of Prentice disclaim any "personal interest whatever" in the treatment of narcotic addicts, and appear to be unfamiliar with so much of what is written and easily accessible upon the medical and scientific problems of the subject. The last report on this subject from the New York Academy of Medicine expresses the opinion that the "whole question of drug addiction needed a dispassionate, thorough-going consideration in its various aspects on the part of the medical profession." The report of the special committee appointed by the Secretary of the Treasury expressed interest in and hope that there would be undertaken "studies to determine the nature of drug addiction with a view of improving the present forms of treatment or evolving new and more efficient methods," etc. Apparently Prentice's "personal interest" lies along other lines. Perhaps that is one reason why so many men who have taken a real "personal interest" in the study of the subject and its medical, public health, and public welfare problems are so abominably "out of step with Jim."

Sometimes it is not wise to go too far and stir things up too much and ignore too long the facts and what a lot of really experienced people and unbiased and responsible publications think about a situation. The Kaiser tried it, and see what happened to him.

ERNEST S. BISHOP, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 21, 1921.

The Rockefeller Foundation.—A dinner was given by the British Government in London on the evening of June 13 to the members of the Rockefeller Foundation, now on a visit to this country for conference purposes. The speech of the evening was made by Mr. Winston Churchill, the Colonial Secretary. Mr. Churchill, in proposing the health of the guests, coupled with the toast the name of Mr. George E. Vincent. The last occasion on which Mr. Vincent conferred with British scientific men was for the purpose of devising means whereby German life might be destroyed. Now they were gathered on a very different errand, the cause not of death but of life, not of destruction but of organization, and of placing all the animals in their proper spheres and cages, from the irritating mosquito which flaunted its wings on the banks of the Niger to the objectionable bacillus which infected the milk of the Malta goat, and the detestable tsetse fly which omitted to brush its teeth and so, when it had taken its breakfast from an unhappy sleeping-sickness-infected native, was bound to transfer that objectionable reminiscence to the next object of its attachment. It all brought them back to the great saying that dirt was good matter in the wrong place. They were not against the mosquito, or the tsetse, or the bacillus, but they wanted them in their proper sphere. In fact, it was no use being against them, because one never knew when they would turn up. Mr. Vincent had been telling him of a scheme which was being developed for uniting cows and sticklebacks in the mission against mosquitoes. The mosquitoes laid their eggs in the grass which overhung the water, and the sticklebacks would like to eat them but could not for the grass, so then they brought in the cows. So the place where the white man was stricken became a salubrious spa. It was all a question of organization. The achievements which scientific bodies had made in this great sphere were well known. Yellow fever had been practically stamped out. Malta fever was wiped out by a simple discovery. Tuberculosis was now being attacked by the Rockefeller Foundation throughout the length and breadth of France. These were wonderful crusades, and they had this feeling in regard to them, that, as they marched forward, they were marching not only on the path of science, but on the path of mercy, along a road which, as they pursued it higher and higher, stage by stage, would set free the human spirit and every form of spiritual activity. So far as the Colonial Office was concerned, he extended to them the same facilities as his predecessors had extended. Everything they could do to

assist the work and further the aims of the foundation would be done, for well they knew how great was the need of their aid in the solution of these problems. How many young Englishmen were ruined every year in their health by the climatic conditions under which they lived! The study of tropical diseases was a work of mercy and urgency similar to that which prompted men to hurry to the seacoast on a stormy night and take the lifeboat out to a ship in distress. It was a line of defense in which all could join hands, friends or foes, wherever they might be found. Science moved forward, and the victory which was gained in any part of the field was immediately shared in every other part. Mr. Churchill ended an eloquent address by saying that all well knew the high and impartial spirit, far above small prejudices and passions, in which this great foundation was administered, and all that the British Colonial Office and the British tropical empire could do to assist their work should in the future, as in the past, be done. Mr. George E. Vincent, in reply, expressed the appreciation of the Rockefeller Foundation, and especially the International Health Board of that Body, for the opportunity the British Colonial Office had offered for work in the tropics and various parts of the world. It had been the privilege of the International Health Board to cooperate with governments in eighteen divisions of the British Empire, and in that work there had been complete enthusiasm and the greatest of persistent good will and kindness. He paid a tribute to the contributions of British medical men in regard to the whole science of preventive medicine and the administration of the public health. Their contributions were of the greatest importance. In America they were accustomed to speak with pride of the work accomplished by Surgeon General Gorgas in the Panama Canal or that of Doctor Heiser in the Philippine Islands. What was the first thing they did? They came to Britain in order to familiarize themselves with the procedure of public health administration worked out so successfully in this country. The difference between the scientific mind and the lay mind was that the scientific mind was always open and never closed. The lay mind liked to jump at conclusions. It was in a scientific spirit that he ventured to suggest tentative conclusions of their experience. They were impressed with the fact that the public health was a unified thing. While there might be a division of tropical medicine, after all the public health was the essential, and the one outstanding thing was the health of the public, and that had to be dealt with in a large, comprehensive, and statesmanlike manner. Their great concern had been to apply the knowledge gained on a large scale, and for this reason they had to ascertain what the problems of administration were and to see what things, theoretically admirable, had to be modified when applied in the mass. They realized that the application of what scientific knowledge they had was an extremely important thing. In these matters they had come to realize that men were vastly more important than money. Unless there were well-trained people to concentrate on the work, money might be a curse instead of a blessing, and they had often been in the position of having more money than people who could wisely utilize it. Therefore, at the Johns Hopkins University a school had been established which had prospered so well that they were promised a full complement of students in the next two or three years. There was also to be organized a school of public health administrators in connection with Harvard University. But, while research was essential to all progress, the work was greatly assisted by practical experience in the field.

Diplomas for Foreign Students in Medical Research at Cambridge.—Dr. P. Giles, vice-chancellor of Cambridge University, sent a letter to the London *Times* of June 14, last, with regard to diplomas for foreign students. He began by referring to the difficulties which face the medical man from a foreign country who desires to pursue research in the medical schools of Great Britain. So far as he is aware, such students have no serious difficulty in obtaining admission to university laboratories where their researches may be pursued with advantage; the difficulty arises in obtaining recognition by means of a degree or diploma for work done. To the knowledge of the writer, the impossibility of obtaining such recognition by foreign students has in some cases been keenly resented. It is pointed out that the real difficulty is that a medical degree in Great Britain constitutes a statutory qualification to practise medicine, and it is obvious that any attempt by the universities to extend their privileges to persons whose previous training was unknown or uncertified by authorities recognized by the General Medical Council would meet with opposition from that body, and rightly so. Consequently, neither a medical degree nor the diploma of public health, which can be taken only by those qualified to practise medicine in Great Britain, is available for foreign students, however distinguished. The University of Cambridge has had the difficulty under consideration for a considerable time, and on June 13, by grace of the Senate, passed regulations for a new diploma in hygiene. The diploma is constituted on similar lines to the diploma in public health, but will be available for foreign students, many of whom, it is believed, are anxious to pursue the study of sanitary science in Great Britain and to return to practise in their own countries with their qualifications attested by a British university. The letter goes on to show that the position with regard to advanced medical or surgical study is different. In a country town, like Cambridge, the number and variety of diseases are not such as to make the university a suitable center for advanced professional study in medicine and surgery; that it is a suitable center for the pursuit of studies ancillary to them is evident from the numbers who wish to come and the resentment that the lack of recognition evokes. For these studies a medical degree cannot be given, but the university has, subject to the approval of the King in Council, established the degree of Master of Science, which will be obtainable only by research and will be open no less to students of medicine than to students of other departments of scientific knowledge.

Oxygen in Mountain Sickness.—Doctor Kellas,

lecturer on chemistry at Middlesex Hospital Medical School, who died suddenly while on the Mount Everest Expedition staff, was educated at Aberdeen, Edinburgh, University College, London, and Heidelberg University. He was a keen mountaineer and deeply interested in the scientific problems involved in his favorite pastime. The difficulties of breathing at high altitudes and the possibility of overcoming them by the use of oxygen had for long engaged his attention, and he had frequently visited the Himalayas to carry on his investigations. Last year he attempted the ascent of Mount Karmet and the winter and spring he spent in mountaineering in Sikkini. He purposed to climb Mount Karmet again this year with a view to furthering his researches into the use of oxygen, but the Mount Everest Committee invited him to carry out his experiments on Mount Everest instead of on Karmet and he accepted the invitation. In expressing their appreciation of his services and experience, which had been placed at their disposal, the committee point out that the use of oxygen for the climbers is not an essential factor of the plans for the expedition, which will not be affected by the deeply regretted death of Doctor Kellas.

1. Diagnostic Pitfalls. The Late Effects of Gassing and Tuberculosis.—John B. Hawes, 2nd., finds that in the endeavor to make an early diagnosis of tuberculosis many physicians, particularly the younger ones, manifest a tendency to make the diagnosis of tuberculosis too frequently. This is true more especially in those men gassed in France during the summer and fall of 1918. In making a distinction between late gas poisoning and tuberculosis it is well to bear in mind the following points: 1. Do not take it for granted that a given process is tuberculous, even with a suggestive *x*-ray. 2. Do not do the reverse. 3. A general appearance of robust health, with marked symptoms, is against tuberculosis. 4. Bear in mind that the lung complications resulting from gas are usually basal and no apical processes. 5. And that the usual signs found are those of a thickened pleura and often a localized bronchitis. 6. And further, that following gas, there is marked to be an increase in nervous symptoms of every kind. 7. Do not take it for granted that these men who have been gassed are *not sick* and do not need treatment, even if you do decide that they have not tuberculosis or, indeed, not much wrong with their lungs in any way. 8. Treat the man who has been gassed and not his lungs.

2. Postoperative Treatment of Urinary Lithiasis.—Edward L. Young, Jr., quotes statistics demonstrating the very high percentage of recurrences in urinary lithiasis which he believes may be prevented to a certain extent by proper postoperative care. Taking into consideration the chemical factors involved, the first thing to do on removal of a stone is to have an accurate chemical analysis made. Whatever the chemistry all the channels of elimination should be kept open. If the stone is calcium oxylate, it is best held in solution by a strongly acid urine, especially when the acidity is due to the double acid phosphate and in the presence of an increased amount of magnesium and with a lessened amount of calcium. Therefore a diet containing a high amount of oxalic acid should be interdicted, and acid sodium phosphate and magnesium may be administered. If the chemist reports a uric acid or urate stone, we know that this form of stone is more soluble in alkaline urine. Therefore meat and meat extractives should be eaten sparingly and salt also should be used sparingly. An abundance of fruit or fruit acids is beneficial. In dealing with bladder stones irrigation is the main thing, and probably does the work by a mechanical process rather than by any means of special drug used. The drugs which may be used by mouth are boric acid, sodium benzoate, acid sodium phosphate, and hydrochloric acid, the two latter agents being the more effective. A sufficient amount of water should be taken whatever the nature of the calculus to insure that the patient shall void two quarts of urine daily. The ideal routine for any patient after operation is to have *x*-rays at regular intervals, short at first and gradually lengthening, if no tendency to stone formation is shown, and at the same time regular pelvic lavage until infection is gone. Make dietetic restrictions sufficiently simple so that the patient will cooperate in carrying them out over a long period of time.

4. Further Clinical Studies in the Use of Mercurochrome as a General Germicide.—Hugh H. Young, Edwin C. White, and Ernest O. Schwartz report their results with mercurochrome-220 during the past two years, and refer to the satisfactory results recorded by others who have used it. They conclude that mercurochrome is a very valuable drug in acute gonorrhea, but the intense pain is a drawback to its use by the patient. Acriflavine is free from this objection and, although not so good a germicide, is often preferable in acute cases. In chronic infections of the urethra, prostate and vesicles, the great value of mercurochrome has been amply proved. It penetrates deeply and may be found in the prostatic secretion several days after posterior instillation. The results obtained in many chronic cases of cystitis are remarkable, long standing infections often clearing up in a few treatments. In some cases which fail to become sterile, constant reinfection of the bladder is found to occur from kidneys or prostate. Mercurochrome is less irritating and produces less reaction in the renal pelvis than silver nitrate solutions, while possessing about equal germicidal powers; but in some cases both drugs should be used alterately, and sometimes silver is better. In some cases of pyelitis, infection comes from the teeth, tonsils, etc., and sterilization of the pelvis is impossible until the primary focus is cured. Continued use has proved it to be a most satisfactory dressing for venereal ulcerations and bubos. In general surgery, reports indicate that mercurochrome is very valuable in dressing open wounds and sinuses. The germicidal efficiency of the drug in

other branches of medicine and surgery has been proved, especially in the treatment of infections of the throat, nose, sinuses, ear and eye, and teeth. It is reported to be most efficient in disinfecting the throats of diphtheria carriers.

8. Blood Pressure Changes During Abnormal Operations.—Alexius McClannan presents a study based on 394 abdominal operations performed by the members of the staff of St. Agnes Hospital, Baltimore. A simple hernia occurring in an otherwise healthy young adult gave the opportunity for studying the effects of surgical operation on the blood pressure without complicating factors. Forty such cases were studied. Nitrous oxide and oxygen caused a rise of from 10 to 30 points in pressure. As a rule this higher pressure continued throughout operation. In about half of the other cases there was no primary change, and the primary rise, when it did occur, was never sustained throughout the operation. In 60 per cent. of cases in which general anesthesia was used the manipulation was accompanied by a fall in pressure. The fall in pressure was most noticed in patients anesthetized under ether. Operation under procaine or procaine nitrous oxide was without change in pressure in 50 per cent. of the cases. In 35 of 50 cases of acute appendicitis opening the peritoneal cavity caused some change in blood pressure. Similarly there was a pronounced effect from manipulation incident to delivery of the appendix. When appendicitis was complicated by peritonitis the sensitiveness to anesthetics as well as to peritoneal manipulations was increased 50 per cent. The reaction to opening the peritoneum was very slightly altered in character, but the manipulations produced marked lowering of the pressure in most cases. In general the blood pressure changes during gallbladder operations resembled those occurring during operations on the appendix. In operations on the stomach the blood pressure fell rapidly when the peritoneal cavity was opened. Hysterectomy gives changes in blood pressure almost the same as those noted in appendectomy. When vaginal and abdominal operations were combined there was a frequent fall in blood pressure after the patient was changed from the lithotomy to the Trendelenburg position.

12. Suturing Blood Vessels, with Report of a Sutured Brachial Artery.—J. Shelton Horsley says that the field for suturing blood vessels is not great. There are, however, instances in which it is indicated as the referable operation, or even the only treatment that should be employed. Collateral circulation develops much less readily in adults after the age of thirty-five than in the young, and there are certain locations in which injury to a large artery is particularly likely to be followed by gangrene. There has been an impression that suturing blood vessels can only be done by a few operators of peculiar skill and that it should not be done by the average "practical surgeon." This is unfortunate, because a technique that can be used only by the exceptional surgeon is not of much real value, and the art of suturing blood vessels may be acquired by any competent operator who is willing to spend some time in experimental work on the lower animals. The technique for suturing blood vessels is that in which broad surfaces of vascular epithelium are approximated and held by a double mattress suture applied under uniform tension. Since the writer published the description of his technique in 1915 there have been no material changes except the substitution of olive oil for petrolatum, since pertolatum and lanolin are all irritating to the peritoneum. Unfortunately olive oil has poor lubricating qualities, and it is necessary to boil the arterial thread and needle in petrolatum and to apply a small amount of petrolatum on the buttons of the suture staff in order to make the thread run smoothly and hold parts in apposition.

14. Experience with More than One Hundred Cases of Encephalitis in Children.—Dr. Josephine B. Neal. (See MEDICAL RECORD, July 2, 1921, p. 35.)

The Lancet.

2. Lettsomian Lectures on Surgery of the Lung and Pleura.—G. E. Gask gives a historical review of surgery of the chest and lung during the past 600 years, which shows that surgery of the chest has at times receded and at times advanced, and that at no period has it made such progress as during the last war. He reviews the development of surgery of the chest during the war, showing how surgeons overcame their dread of opening the closed thorax and learned to repair a wounded lung and restore it to its normal function. It has also been demonstrated that in civil practice it is possible with safety to the patient and without expensive apparatus to open the chest widely and to deal with discarded processes which were previously unrelieved. Evidence is brought forward to prove that the operation of thoracotomy is a sound and reasonable one. The writer submits that more and more operations on the chest should be undertaken and that with a wider experience the operation of thoracotomy will become as useful and ordinary as that of laparotomy.

3. The Operation of Ventrofixation with the After Results of 220 Cases.—J. E. Gemmell and A. Leyland Robinson endeavor to show that a properly performed ventral fixation is free from undue risk, does not interfere with subsequent pregnancy or labor, and in a large majority of cases permanently cures the patient of those symptoms for which operation is undertaken. The operation they recommend is as follows: Through a 2 or 3-inch median incision the peritoneum covering the bladder is picked up in the middle line with a succession of Spencer Wells forceps arranged in file and extending from the utero vesical attachment to the upper border of the symphysis pubis. Using these forceps as guides, a catgut suture is inserted in the center of the uterovesical fold and continued as a running stitch through the peritoneum covering the bladder, passing downward, forward, and upward in the middle line until the paricta peritoneum is reached at the lower angle of the wound. This stitch is both continuous and interrupted, the two ends being knotted at short intervals, thus bunching the peritoneum into one mass and forming a median septum stretching across the uterovesical pouch between the uterus and the abdominal wall; the two ends of the suture are finally brought through the rectus fascia on each side, just above the symphysis pubis. This septum effectually obliterates the space which would otherwise exist below the fixation area. It is merely a safety device and not intended to act as a uterine support. The uterine wall immediately related to the uterovesical fold of peritoneum is part of the lower uterine segment; its function during labor is passive dilatation. Examinations during cesarean section have failed to show any elevation of the level of this reflection. The anterior surface of the uterus immediately above the attachment of the uterovesical reflection of peritoneum is therefore selected as the fixation point. This type of ventrofixation is a simple and useful operation for a bulky, tender, fixed retroverted uterus, such as frequently follows labor and some degree of infection. Postoperative intestinal complications do not occur. In this series of 20 cases, 179 patients described themselves as cured (including 43 women with 72 pregnancies). Forty-one patients complained of symptoms due to factors beyond the control of the surgeon, namely, labor, over-exertion, recurrence of infection, the menopause, and neurosis.

4. The Treatment of Urinary Incontinence by Electrical Methods.—F. Hernaman-Johnson finds that taking all types of patients, at all ages, a cure of urinary incontinence by a combination of electrical treatment and suggestion may be expected in about 50 per cent. of the cases. The simplest method of making the electrical application is to introduce a metal bougie into the bladder and pass a faradic current through it up to the patient's limit of tolerance. A second method is to fill the bladder with a weak solution of zinc

sulphate and pass into the bladder a rubber catheter containing a wire of soft metal. Care must be taken that the wire does not come in contact with the wall of the bladder or urethra. A current of 10 to 15 milliamperes is then passed for ten minutes. A pad is placed beneath the patient to form a negative pole. This procedure may be repeated every day for a fortnight. The time required to effect a cure in favorable cases is about a month.

2. The Relation of Heart Disease and Pregnancy.—Sir James Mackenzie, in summing up his four lectures in this subject, says that as the danger attending pregnancy in women with heart disease is the occurrence of heart failure, the physician must keep clearly before him the symptoms by which this can be recognized. An absence of a clear conception of the nature of these symptoms has too often led to a misunderstanding of their significance. No sign manifested by the heart itself gives information as to the functional efficiency of the organ, and consequently the signs of heart failure must be looked for in other directions, and more especially in those structures whose blood supply is likely to be reduced by the weakening of the circulation. Extreme heart failure is shown by such signs as dropsy, enlargement of the liver, edema of the bases of the lungs, or cyanosis. Early heart failure may be revealed by no sign when the body is at rest, and may only be discovered by distress evoked when some effort is made which the patient was wont formerly to perform in comfort. The signs of distress, so far as women in the child-bearing period are concerned, are breathlessness and palpitation. Pain on effort may be present in certain cases of mitral stenosis and aortic disease, but as a rule the pain of grave heart failure is a sign which occurs much later in life. From this it follows that no single sign shown by the heart itself, however abnormal it may seem, should be a bar to pregnancy. If they occur in hearts that show no other abnormal sign, and if the patient's response to effort is good, they should be ignored. If they are associated with other signs of heart disease the prognosis should be based on these signs and not on the systolic murmurs. The same rule applies to the irregular actions of the heart due to respiratory arrhythmia and extrasystole. In women with easily excitable hearts, who suffer at times from pain of varying degrees of severity (the neurotic heart or the toxic heart), when the organ is normal in size, or only slightly enlarged, the heart trouble constitutes no bar to pregnancy. This applies whether systolic murmurs are present or not. The form of heart disease which gives most occasion for anxiety in pregnant women is mitral stenosis. This usually has followed an attack of rheumatic fever. In such cases great care must be taken to differentiate between dangerous and not dangerous forms of the malady. The latter include instances in which the cicatrizing process, which produces the stenosis, is stationary or is only progressing slowly. Such slow progress is shown by the character of the murmur. If there is present ten or fifteen years after the causative attack of rheumatic fever only a presystolic murmur, and if the heart's size is normal, its rate regular, and the response of the patient to effort good, then pregnancy may be undertaken with a fair prospect of safety. If, on the other hand, there is present within a few years of the causative attack of rheumatic fever, a diastolic murmur as well as a presystolic, there will be danger. This will be particularly the case when there is evidence also of the heart muscle being damaged—that is, enlargement of the organ and much distress on effort. When in addition to the mitral stenosis there is fibrillation of the auricle, pregnancy should be forbidden. If pregnancy has taken place then the case should be watched; and if grave signs of heart failure occur, pregnancy should be terminated. In cases of aortic regurgitation, if the heart is normal in size and the response to effort is good, pregnancy may be undertaken. If, on the other hand, the ventricle is much hypertrophied, and there is marked "Corrigan" pulse, the probability is that the heart will be so permanently impaired that it will cripple the patient severely if she gets over her confinement.

1. Remarks on Radium Therapy in Uterine Cancer. A. E. Heywood Leach.
2. The Treatment of Acute Pyogenic Infection of the Knee-joint. A. H. Southam.
3. The Results of Ninety-eight Cases of Nerve Suture. Paul G. Dane.
4. Five Cases of Rat-Bite Fever. Two Cases Successfully Treated by Neosalvarsan. P. W. Easton-Fanning.
5. The Treatment of Cutaneous Anthrax. W. H. Ogilvie and A. W. Hall.
6. Cryptogenetic Pneumococcal Septicemia. Sir John Lumsden.

2. The Treatment of Acute Pyogenic Infection of the Knee-joint.—A. H. Southam has had little success with the Willems treatment of acute suppurative arthritis, and finds it very difficult to persuade patients to move an acutely inflamed joint. A method which has given better results in his hands consists of thorough irrigation with saline in an early stage, followed by the application of bipp. The insertion of drainage tubes into the knee joint he considers not only unnecessary but harmful. The joint cavity must be left open after the irrigation, otherwise pus will accumulate under pressure, and, burrowing through the capsule, spread in the fascial planes. Extension must be applied to the limb during the early stages. Mobilization and massage must be instituted as soon as the stage of active inflammation has subsided, usually within fourteen days.

3. The Result of Ninety-eight Cases of Nerve Suture.—Paul G. Dane reports failure in about 50 per cent. of this series of ninety-eight cases of nerve suture. The explanation of these failures he says involves many factors, such as concomitant injury to the blood vessels and other nerve trunks, and improper preoperative and postoperative treatment. In practically every failure there has been neglect of preoperative and postoperative postural treatment by means of splints, etc. This is especially true in regard to the delicate intrinsic muscles of the hand, which are easily pulled out of position by the contracture of antagonistic groups. With regard to postoperative treatment, the writer has not been much impressed with electrical methods, and in the future will employ them not at all or only to a limited extent. There is one thing which these cases require above all, and that is complete rest, which can only be secured by the application of appropriate splints, and later gradual reeducation of muscles that have been injured by denervation.

5. The Treatment of Cutaneous Anthrax.—W. H. Ogilvie and A. W. Hall quote from a circular issued by the Ministry of Health, in which the serum treatment of anthrax is recommended and the statement made that incision is unnecessary. To this statement the writers take exception. A series of cases treated at Guy's Hospital gives evidence that the death rate when both methods are combined is notably lower than when either is used alone. Excision by itself will assure a cure in about 90 per cent. of cases in a disease having a natural mortality of something like 50 per cent., while serum at best cannot be relied upon to avoid a fatal issue in all cases. Excision and serum treatment is probably the most rational and the safest course in all cases of cutaneous anthrax which have not reached the stage of septicemia.

3. *Giardia* (Lamblia) *Intestinalis*. A Common Protozoan Parasite of Children. Kenneth F. Maxcy.

3. Giardia (Lamblia) Intestinalis. A Common Protozoan Parasite in Children.—Kenneth F. Maxcy undertook the study reported in this communication to determine the frequency of this parasite in the intestinal tract of apparently normal children in the United States. In pursuing this study attention was directed toward demonstrating only the encysted Giardia, and incidentally the other common intestinal protozoa which show encysted forms, viz., *Entameba, coli, Entameba histolytica, Endolimax nana, Chilomastic* (Tetramitus) *mesnili*, coccidia, and blastocystis. The specimens were obtained for the most part without the previous administration of a cathartic, and were usually formed stools. Two "wet smear" preparations were made from each specimen, distilled water being used. Material for the one was scraped from the exterior of the stool, any clumps of mucus visible being included; material for the second was taken from the interior. A drop of 1 per cent. water soluble eosin was added to the preparation. The field took a pink stain; the viable cysts remained unstained and stood out rather sharply as clearly defined, pale green, refractive ovals against the pink background. Whenever cysts were found to be present another preparation was made and stained with iodine (iodine 1 part, potassium iodide 2 parts, distilled water 100 parts). This solution differentiates the structures a little more clearly and brings out the iodophilic inclusions. When possible each patient was examined on two occasions at intervals of two or more days. The children examined were miscellaneous medical admissions. Excepting a small group of "feeding cases," these children were admitted because of acute infectious disease, and were free from gastrointestinal disturbance. Of the total of 89 children examined, 18, or 20 per cent., were found to be harboring intestinal protozoa of some type. It is noteworthy that in a group of 15 "feeding cases" under one year of age no infestations were found. The youngest positive case was a little girl 17 months of age whose stools showed large numbers of *Entameba coli* cysts. From the second year on there was an increasing number of positive cases with advancing age, so that the group of children from 6 to 12 years old showed a decidedly higher percentage of infestations than the children between one and five. *Giardia intestinalis* (alone) was found in ten cases; *Giardia* and *Entameba coli* in one; giardia and blastocystis in two; giardia, *Hymenolepsis nana* and *oxyuris vermicularis* in one; *Entameba coli* (alone) in four. The most interesting fact brought out by the study was the large number of children who harbor *Giardia intestinalis*. The percentage of infestations appears to be much higher in childhood than in adult life.

1. Streptococcic Osteomyelitis of the Temporal Bone. Harry Boyd-Snee.
2. Eye Injuries in Relation to Industrial Organizations and Insurance. No 3. Walter N. Sharp.
3. Eye Conditions of Interest to the Man in General Practice. Joel Whitaker.

1. Streptococcic Osteomyelitis of the Temporal Bone.—Harry Boyd-Snee draws the following conclusions from an experience based chiefly on the observation of 258 cases, the majority of which were encountered in the United States Army Base Hospital at Camp Pike, Ark., during the period from November, 1917, to March, 1919: (1) Streptococcic osteomyelitis of the temporal bone is a clinical entity and is to be diagnosticated as such. (2) The etiological factor is the streptococcus microorganism. It is identified as a Gram-positive diplococcus, cultures from which the pneumococcus has been excluded by test show typical chain formation, and are typed as *Streptococcus mucosus capsulatus, Streptococcus hemolyticus* and *Streptococcus nonhemolyticus*. (3) Recovery of the streptococcus organism from the tympanic exudate in a case of otitis media, either acute exudative or acute suppurative, is sufficient evidence to support the diagnosis. (4) The diagnosis is an absolute indication for immediate operation. (5) Closure of the wound, partial or complete, should never be done.

Wiener klinische Wochenschrift.

March 31, 1921, xxxiv, 13.

Narcolepsy.—Somer concludes a continued article on this subject which contains an account of two personal cases. In regard to true narcolepsy the sleep of this affection should be natural and preceded by fatigue. The subject may fall asleep in any position, with preference for positions in which ordinary subjects are most prone to fall asleep. The depth and duration of sleep are by no means constant and depend on external circumstances. There was the suggestion of cataleptic inhibition, while an affective frame of mind as well as the phenomena of overexertion were seen. Thus one man when on the point of angrily beating his son was seized with the phenomena of muscular relaxation. It is well known that catalepsy frequently supervenes amid affective behavior. Affects are associated with peculiar vasomotor behavior and in one of the author's cases the face was flushed during sleep while the other patient showed, instead, pallor. Both subjects showed pupillary contraction, slow pulse, and other evidence of exhaustion of the sympathetic system. If the totality of cases is considered many vasomotor phenomena could be quoted. There is, in fact, a liability of the vasomotor center in these narcolepsies. Several writers see in genuine narcolepsy a disturbance of endocrine secretion, and especially of that of the hypophysis. On the other hand, in certain cases of symptomatic narcolepsy it might be more fitting to accuse this gland in connection with organic disease of the sella which has been diagnosticated in at least one case *intra vitam*, and once at autopsy. Extreme overexertion with accumulated fatigue toxins simultaneously affecting the endocrine glands and vasomotor center might explain attacks in the predisposed. The author believes that the autopsy table will yet explain the mystery of this affection, for thus far it has not occurred in a lethal setting to any great extent.

Gazette des Hopitaux.

April 12-14, 1921, xciv, 29.

Repopulation of France.—Dr. W. W. Keen of Philadelphia contributed this article at the time of his presidency of the V. International Congress of Surgery, held last July in Paris. It appears to have been composed as a reply to a request by the editor for Keen's personal opinion on the subject of repopulation. He first cites two French laws which relate to illegitimacy of French children. The first has to do with legitimizing children born out of wedlock, and the second would give to the mothers of such children the status of legal wives, including the right to bear the name of the father. The agitation for these laws was the result of the sudden mobilization to meet the German invasion, for it was evident that dispensing with formalities in a very large proportion of these cases was not deliberate immorality, and that in times of peace such formalities would have been forthcoming. Many fathers of such children died on the battlefield and deserved to have their war infants legitimized. Of the two laws, that which deals with the children is already in force and has the author's approval. In regard to the second proposed law, not yet established at the time of writing, it would in the author's opinion be an injustice to the mother to refuse legitimacy to her when it had been granted to her child. But now that the war is over the author is not in favor of legitimizing the children and mothers in times of peace. Instead, he would sanction the opposite course of illegitimizing the father. In regard to race suicide, one of the chief causes is that children are now a liability, whereas not many years ago they were an asset—a good investment. The only way to restore the *status quo ante* is for the state to make it an object for the parents to bear children. A subject much agitated recently is telegony, the existence of which has been accepted by some animal breeders. Women of France who have been forcibly impregnated by Germans have a certain fear that further offspring might exhibit Teutonic traits. Keen quotes from Conklin of Princeton that telegony is a myth and that none of these women has anything to fear from bearing children to Frenchmen.

Book Reviews.

DIAGNOSTIC AND THERAPEUTIC TECHNIC. A Manual of Practical Procedures Employed in Diagnosis and Treatment. By ALBERT S. MORROW, M.D., late Lieut.-Colonel, M.C., U.S.A., Attending Surgeon to the City Hospital, and to St. Bartholomew's Hospital, New York City; Consulting Surgeon to the Nassau Hospital, Mineola, L. I. Third Edition, Entirely Reset. Price, $8.00. Philadelphia and London: W. B. Saunders Company, 1921.

THIS volume was originally intended for the use of the hospital interne and the general practitioner, to be supplemented for special use by referring to the larger textbooks. The author has gathered and brought together information from a number of books and from practice, and has performed a valuable service to his profession. All the procedures have been given in detail and as a result the volume is of great value, which only requires to be supplemented by practice. Nothing really essential to the purpose has been omitted. The fact that a third edition has been called for, speaks for the value which has been found, and the careful revision and additions have together brought it thoroughly up to date.

PRÉCIS DE RACHIANESTHÉSIE GÉNÉRALE. Par G. LE FILLIATRE, Chirurgien de l'Infirmerie Centrale des Prisons de France, etc. Prix 8 francs. Paris: Libraire E. Le François, 1921.

THIS is a 16mo volume of 126 pages, with 29 illustrations. There is a preface by Victor Panchet, the well-known authority on the subject matter, in which the method of the author is warmly commended for its simplicity. The technique is so standardized that the method is applicable at any level. The work has nine chapters devoted to history, evolution of spinal analgesia, anatomical considerations, technique (under seven subdivisions), duration and progress of analgesia, incidents of the method, failure and accidents, examination of spinal fluid, contraindications and points of superiority over other anesthesias. Were it not for the comparative indifference to spinal analgesia in this country the volume would deserve a translation, conversely a translation might stimulate interest in the method.

ATLAS DE SYPHILIMÉTRIE (100 GRAPHIQUES). Les Conditions Experimentales de l'Extinction de la Syphilis. Par ARTHUR VERNES, Directeur de l'Institut Prophylactique de Paris. Paris: P. Boll, 1920.

THIS atlas, so-called, is devoted, as the title indicates, to the march of the seroreaction, as that it is made up entirely of graphics of curves. Blood and spinal puncture curves are given and the influence of various kinds and plans of treatment. The activities of the Institut Prophylactique form a brief supplement. A feature of the *graphiques* is their length, for some of them go back to the early days of serodiagnosis, and are brought down to date. Graphic No. 35 begins in June, 1911. The seroreaction was negative for a brief interval in September, disappeared again in June, 1912, and, under periodic testing, has been negative for the past eight years. Disease curves extending over nine consecutive years must be unique and appear to justify the use of the term syphilimetry.

L'ANNÉE THÉRAPEUTIQUE. Par LE DR. L. CHEINISSE, Charge du "Mouvement Thérapeutique" dans la *Presse médicale*, ancien redacteur de la *Semaine médicale*. Année 1920. Paris: Masson et Cie., 1921.

THE author has made these contributions to medical journals for the past ten years but this is the first time that they have been reprinted in book form. The arrangement of topics is alphabetical, beginning with acidosis and ending with vertigo of Menière. The subjects in this series are limited to diseases, but there is a brief series of supplements on drugs and technique. The general plan is simple. Under the heading of the diseased condition the remedies of the year are discussed. The author does not indorse them and hardly comments at all. Under another are mentioned vaccination (specific and nonspecific) and benzoate of benzyle. Under epilepsy are discussed Borno-potassic tartrate and luminal. The method notably restricts the responsibility of the writer, and makes him a news distributor rather than a censor.

THE STORY OF THE AMERICAN RED CROSS IN ITALY. By CHARLES M. BLAKEWELL. Illustrated and containing 253 pages, including appendices. New York: The Macmillan Company, 1920.

FROM the begining Italy's role in the World War was marked with spectacular activity. For two years before America entered the strife, Italy's resources were becoming exhausted, her man power was gradually depleting, and her need for medical aid was urgent and great. It is at this time that the story of this instructive volume begins; not a history of bringing charity to a nation, but one of alleviating, through justice, the sufferings brought on by twenty-four months of incessant warfare in the common cause of the allies before our own country took up arms.

The activities of the American Red Cross extended to the principal cities of Italy including Genoa, Turin, Milan, Padua, Venice, Florence, Rome, Naples, Calabria, Sicily, and Sardinia. Some of the war's aftermath, more especially tuberculosis, is discussed, and the measures of offsetting the economical and human disasters incident to these conditions are rehearsed.

The book is in no sense statistical but narrates in interesting fashion the historical activity of the American Red Cross organization actuated with an enthusiasm common to America and Italy and inspired by common ideals.

AMERICAN RED CROSS WORK AMONG THE FRENCH PEOPLE. By FISHER, AMES, Jr. Containing 178 pages and 8 illustrations. New York: The Macmillan Company, 1921.

THIS work is a descriptive résumé of the activities of the American Red Cross among the French people during the period of the war and the months immediately following. It is stripped of all technical rehearsal and deals only with the broad character and scope of American Red Cross efforts. Beginning with Paris, the outlines of the activities are presented, extending soon into the French hospitals and the canteens at the front. The description includes also a discussion of the mutilated and maimed and extends to the indirect effects of war, the suffering children. Activities in French cities other than Paris are briefly reviewed, the book ending with a rehearsal of the scourges of the white plague that affected the war-worn and health-depleted French.

In no way does this volume pretend to be a full and exhaustive treatise of Red Cross activities; but it presents only such salient features of the beneficent accomplishments of this organization, familiar alike to those who shared in its activities during belligerent times and to those who contributed in effort and assiduous zeal to its triumphant success.

DISEASES OF THE SKIN; a Text-book for Students and Practitioners. By J. M. H. MACLEOD, M.A., M.D., F.R.C.P., Physician for Diseases of the Skin, Charing Cross Hospital; Physician for Diseases of the Skin, London Hospital for Tropical Diseases; Physician to the Skin Department Victoria Hospital for Children; Lecturer on Dermatology, Charing Cross Medical College and London School of Tropical Medicine; formerly Editor of the *British Journal of Dermatology*, etc. Price, $16.00. New York: Paul B. Hoeber, 1921.

THIS book of considerably over 1200 pages is a most complete treatise on diseases of the skin, written for the guidance of the general practitioner chiefly, though there is much in the book, especially in the illustrations, which will prove helpful to even the experienced dermatologist. The illustrations are worthy of special mention; there are four hundred and thirty-five of them in the text and on plates, in addition to twenty-three colored pictures on plates, most of them original or from sources not familiar to American readers. The classification followed, so far as possible or practical, is an etiological one, although at times it is found necessary to form a regional grouping or one by the character of the lesions. The text is as commendable as the illustrations, and the combination of the two makes clear what to the non-optimist is usually a difficult subject. The book is a valuable addition to dermatological literature.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-sixth Annual Meeting Held at Atlantic City, May 10 and 11, 1921.

DR. W. S. THAYER OF BALTIMORE, PRESIDENT, IN THE CHAIR.

(*Concluded from page* 128.)

Second Day—Wednesday, May 11.

Dr. A. D. HIRSCHFELDER of Minneapolis asked if Dr. Wolbach had met with fever or other manifestations as the result of individuals feeding apparently normal lice from an apparently normal source. When they were working on the development of substances to kill lice they had an experience which they were not able to find duplicated in the literature. Professor Moore, the entomologist, was feeding about 2000 lice per day, and came down with what seemed to be German measles when there was an epidemic of that nature. A few months later he had a second attack break out with a second rash. He had glandular enlargement with some fever. They then studied the effect of feeding lice on volunteer workers and took careful records of the temperature. The lice were grown from eggs taken from the Minnesota lumber camps. Three out of four individuals developed fever and glandular enlargement, and they found an eruption similar to German measles. The fever came on within an hour after feeding. One individual who took exercise had a temperature of 103°. Four individuals had a slight fever without glandular enlargement. Three out of four had fed lice during the previous summer and they thought that there was some phenomenon of hypersensitiveness to account for the three individuals having had a greater reaction than the four who had never fed lice before. They had been able to find fever as the result of feeding apparently perfectly healthy lice. The permanence of the reaction and substances indicated that it was not trench fever.

Dr. EMANUEL LIBMAN of New York said that before discussing the question of *Rickettsia prowazekia*, he would like to go back a little bit and discuss Dr. Wolbach's work. They should see if there was any relation between this organism and the bacillus of Plotz found in 53 per cent. of the endemic cases in New York and in Russia in 100 per cent. It occurred early in the disease. It was never found in the blood in infected animals, but it occurred in the blood of human beings 36 hours after the crisis. The blood was then no longer infectious for animals. In two cases in Russia the epidemic typhus-fever bacteria were the same as those in the endemic cases. In the endemic cases there were 0.7 colonies to the cubic centimeter of blood, and in the epidemic cases 1.5 c.c. There were 168 colonies in 12 c.c. of blood in one case studied by Dr. Baer in Russia. The organism was constantly found in typhus, but not after the blood had ceased to be virulent. Some years ago Anderson and Goldberger infected guinea pigs with the virus, and kept a strain three and one-half years. Then it was put into a monkey and they got typhus. The blood of the monkey gave the typhus virus. The organism might then be called a concomitant invader. In typhus fever there was a reaction against proteus X 19, that reached a height at the crisis and then disappeared. All the immune reactions were not present before the crisis; they were increased after the crisis and were highest at the end of the second week. In guinea pigs there was no complement fixation and no agglutination, but after the crisis in guinea pigs, and in human beings after the crisis one could get the Dale reaction. On account of accidents the cross immunity tests could not be made. In Mexico Dr. Olitsky found typhus bacilli in nine groups of lice, which seemed to be a virulent type. What then was the relation to Rickettsia? The Plotz bacillus was Gram-negative the organism was found in lice as a Gram-negative bacillus, but became Gram-positive later. Were Rickettsia bacteria? Were they identical with the Plotz bacillus? Evidence so far showed that it was probable that Rickettsia were bacteria. If one took the Plotz bacillus in the Gram-negative state and transferred it to fluid media, one got an organism indistinguishable from Rickettsia, that was Gram-negative. The next generation would stain with blue. When one got back to the solid medium it was Gram-positive. If one used a fluid medium the organism stained pink with Gram. It did not take aniline dyes. There was no proof that Rickettsia were not bacteria. Those who grow Rickettsia from lice must prove that they were not typhus bacilli.

Dr. R. P. STRONG of Boston said that from Dr. Wolbach's investigation one must regard Rickettsia as a group of microorganisms of which two species were pathological for man, one giving rise to typhus, the other to trench fever. There was a third species, apparently saprophytic for man, and there might be others occurring in the gut of normal lice. There might also be parasitic ones.

Dr. THEOBALD SMITH, Princeton, N. J., asked if Rickettsia had been transmitted to the egg of the host.

Dr. H. NOGUCHI of New York City said that in looking over the microphotographs, it seemed to him that the arrangement of the bodies was like that of chlamydozoa. There was an intracellular invasion by the organism, indicating morphological changes. Trachoma bodies also had cell inclusions; when they entered the cells they seemed to break off into minute granules. They took Giemsa stain. This might be a special group of organisms, not bacteria, but there were similar morphological changes in other organisms. Trachoma bodies occurred in two forms: (1) Large triangular bodies staining blue; (2) at the stage of conjunctivitis, they appeared as very minute diplococci.

Dr. HOMER F. SWIFT of New York City said that a similar experiment was performed with Rickettsia by the British. The lice were placed upon a patient with trench fever. Part of them were kept at a temperature of 30° C. Another group were kept at 15-17° C. Those kept at 30° C. developed Rickettsia and the others did not. Both sets were infectious by the subcutaneous test, therefore Rickettsia might be a degeneration form of cells. He did not believe that personally, but that was the experiment done.

Dr. N. E. BRILL of New York asked if they saw any relationship between Rickettsia and the bodies found in Mexico in the dermacentor typhus.

Dr. WOLBACH, in closing, said that none of them had any ill effects from normal lice, even from as many as 2000. After completing controls to their own lice they took lice from Polish people, collected from the public bath house. Mr. Baker collected these. He became ill. Before his illness they found Rickettsia in the lice. They were of the extracellular type. He had a typical case of trench fever. It was a matter of thirteen or fourteen days when the Rickettsia bodies began to appear. Sections were made of these lice. Mr. Baker, after his recovery, continued to infect clean lice with these bodies. Dr. Libman had brought up many interesting questions. They made one series of attempts to cultivate the Plotz bacillus, using ascitic fluid. There were thirteen early cases at the end of the second week. They made cultures by the Plotz method, controlling the cultures with other tubes, without the addition of blood. They used anaerobic broth culture, and got cultures in 50 per cent. Some were contaminations. The late stages of the disease showed a high percentage of streptococci. The attempts were not adequate controls of Plotz's work. Dr. Libman has laid more stress on tinctorial reactions than they did. The Giemsa stain was a tricky stain; one could make it blue or pink, according to the fixative used. They were forced to drop work on many points, such as the immunological side of the work, and to stick to work which was regarded as crucial. There were some inconsistencies, but the Plotz bacillus and Rickettsia might prove to be the same organism. There were astonishing things in biology. There was a sequence in the development of Rickettsia in lice that made them regard them as distinct from ordinary bacteria. To take up Dr. Swift's question, they found great difference in the Rickettsia according to the degree of temperature. Examination of lice for Rickettsia required very careful search. Dr. Todd's patience was monumental in this work. Often there was a large form coiled in the cell. In the second stage, the bacillary forms, there was an enormously distended cell with minute forms.

That was characteristic of the group. Bacot had reported a similar organism in bedbugs in England. The filamentous forms in smear preparations stained bluish with Giemsa. They broke up into granules. One might use the direct method of settling the question by making a few experiments injecting the eggs. One worker found infected eggs in the Mexican typhus. As to chlamydozoa they were probably similar, but there was no relation to the streptococci in trachoma.

Experimental Pigment Cirrhosis and Its Relation to Hemochromatosis.—Drs. F. B. MALLORY, FREDERICK PARKER and ROBERT N. NYE, Jr., of Boston presented this topic. Dr. Mallory said hemochromatosis was a rare disease. When the pigment appeared in the skin, in the earlier stages it was common. In a large number of autopsies (1465), including cirrhosis (alcoholic, syphilitic, infectious), acute yellow atrophy, etc., pigment was frequently found in the liver. In the alcoholic cases it was found in 50 per cent. The liver cells became packed with hemosiderin up to a certain stage, then suffered necrosis. The endothelial leucocytes took up the pigment and deposited it in the periportal tissues where it remained for years. Later the heart, pancreas adrenals, fatty tissues, and skin became pigmented. In experimental work the pigment could be produced in animals by definite chemical substances. Cirrhosis of the liver occurred in a few months and the animals died quickly, as the bile became very toxic. This state was produced by the combination of certain metals, such as copper, with hemoglobin. The copper salts acted on the liver, and the combination with hemoglobin on the heart. Now that prohibition was in vogue and private stills were common, one might expect to see more of this disease in the human subject in the near future.

Dr. N. F. BRILL of New York asked if the doctor saw any difference in the pigment from that found in pernicious anemia in the spleen and bone marrow. In hemachromatosis there was no increased destruction of the red blood cells, such as occurred in hemolytic conditions.

Dr. L. G. ROWNTREE of Rochester, Minn. asked if the doctor saw any evidence of toxicity from the copper salts. Were there any blood changes?

Dr. T. SOLLMAN of Cleveland, Ohio, said he would like to understand the effect of copper salts on the blood pigment; he thought they converted the hemoglobin into hematoxylon.

Dr. F. B. MALLORY, in closing, said that copper salts did not affect the red blood corpuscles at all. Lead would kill the red blood cells, copper salts did not. On the other hand, physiologists said that a large number of red blood cells were destroyed every day, so there must be free hemoglobin. This was taken up by the copper salts, and became a toxic agent because it was insoluble. There was no enlargement of the spleen, and no effect on the bone marrow cells.

Some Novel Effects Produced by Stimulating the Nerves of the Liver.—Drs. W. B. CANNON, J. E. IRIDIL, and P. E. SMITH of Boston presented this paper. They said that the denervated heart could maintain its function as long as the temperature was uniform. Stimulation of the hepatic nerves increased the rate of the denervated heart. This rise was due to some substance given off by the liver itself; probably aminoacids supplied by the intestinal tract, and taken into the liver, were given off again by this organ.

New Evidence of Thyroid Secretion Following Stimulation of the Cervical Sympathetic.—Drs. WALTER B. CANNON and P. E. SMITH of Boston presented this paper. They found that if the cervical sympathetic nerve were stimulated with the thyroid nerve in, adrenalin would raise blood pressure more quickly. This did not occur if the thyroid had been removed. By use of the denervated heart it was possible to get evidence of control of the thyroid and to get reflex response. With slight stimulation of the gland for two minutes the heart rate was considerably increased after ten minutes. The submaxillary did not cause this effect. It made no difference if one removed the adrenals or not.

Dr. H. SEWALL of Denver asked if the author had made any observations on the volume of blood entering the heart? Was it increased? That would explain the increased pulse rate on other grounds.

Dr. CANNON, in closing, said they had gone carefully through the literature and had failed to find variation due to the flow through the coronary arteries. These statements were thoroughly supported by numerous observations of their own.

Experimental Studies of the Pharmacology of Quinidine.—Drs. A. E. COHN and R. L. LEVY of New York presented this communication. They quoted one patient who said that his cardiac attacks (auricular fibrillation) were stopped by taking quinine. It was tried on other patients, with success in some cases. Other derivatives of the drug were studied in order to stop fibrillation. Quinidine gave success in 50 per cent. of cases. Experimental studies on dogs showed that contraction of the auricle became less, and that with faradization after quinidine dosage, one could not start fibrillation. Other effects noted were increase of height of contraction and fall of blood pressure in the peripheral arteries. There were no constant results on the T-wave or on the conduction time. The conclusions were that there seemed to be an alteration in the muscle which made it refractory to faradization as regards fibrillation, and there was a striking effect on contraction. These were artificial experiments, not likely to be carried into the clinic. Experiments were now being made as to the effect of the drug on the fibrillatory process.

Dr. A. D. HIRSCHFELDER of Minneapolis said he would like to ask if the speaker also tried atropine on the heart after the fibrillation had been stopped by quinidine. In 1908 he was able to show that some, but not all, cases of experimental fibrillation to faradic stimulation of the vagus were stopped for a time. The beneficial effect of slowing of the heart by digitalis did not stop the fibrillation, which was largely a vagus effect and could be cut off sharply by atropine. In the laboratory they had cut it off by nicotine which slowed the rate of the ventricle, without stopping the fibrillation as a not peripheral central effect.

Dr. G. C. ROBINSON of Baltimore said that to throw some light on the problem one must know why the auricles fibrillated and what was the mechanism of the fibrillative movement. The auricles were affected by a chemical substance and the tendency to fibrillation reduced. In an experience he had with a patient who was poisoned by hydrogen sulphide, he noted the fibrillation lasted two days and the rhythm then became normal. There was no evidence of cardiac lesion or disturbed circulation, so that fibrillation could be induced. It had been a problem to determine why diseased hearts got into fibrillation and an attempt had been made to find a lesion that might be responsible. An anatomical lesion was not necessary to alter the fibrillation of the auricles, either to get into or out of this state.

Dr. A. E. COHN, in closing, said that the dose of this drug clinically was one of 0.2 to 0.4 gram, to test for drug idiosyncrasy, and then administration at half-hour intervals of 0.4 gram doses by mouth, and usually the effect had been obtained by a total dosage of 1.2 grams.

Dr. ROBERT L. LEVY of New York, in closing said that they had administered atropine after quinidine, and in these patients there was no return of fibrillation.

The Relation Between Obstruction to Pulmonary Ventilation and the Size of the Lungs.—Dr. C. F. HOOVER of Cleveland, Ohio, read this paper. Biermer had studied asthma in 1875, and supposed it to be a vicious circle caused by active compression of the lung in the expiratory phase. Bronchial spasm was an impairment of the compressibility of the lung. Against this theory were the facts that one could have pronounced emphysema, and expiration might be passive, not active. There might be another phase. After taking adrenalin the patient was relieved of bronchial spasm, which did not fall under the all-or-nothing law, but one might have partial spasm, or hypertonus of the bronchi. Adrenalin raised the vital capacity with disappearance of the symptoms, and removal of the abnormal respiratory excursion. Did active expiration produce expiratory dyspnea? This did not take place in experiments on animals. Could a patient have an increased volume in the lung with resistance in the trachea? One did not often see incomplete tracheal

stenosis. In one patient where this existed there was no change in lung volume. One man had aneurysm of the arch of the aorta compressing the trachea, and he lifted the aneurysm in the expiration, which was broken into sharp hisses. The volume of air was not increased in the lung; there was no emphysema. In another patient with aneurysm of the descending arch of the aorta with compressed bronchus, on lying down there was reduction of the vital capacity to 1200 c.c. The left diaphragm lifted and then the right. The left lung was stabilized, but when upright they were equal. Lying down he had expiratory dyspnea. Dr. Hoover said emphysema was not equally distributed over the lung, because there was not equally distributed hypertonus of the bronchial tree. Adrenalin affected the entire bronchial tree, but clinical asthma affected parts of the bronchial tree unequally.

Dr. H. SEWALL of Denver said that in 1859 Gaertner studied pulmonary conditions and thought that this one was the result of inspiratory obstruction. This should be taken into consideration. Dr. Hoover spoke of displacement of the diaphragm; in clinical observations they did not pay attention to the physiological feature of diaphragmatic action—or tonus. In a very septic patient there was liver dulness at the fourth rib on the right. Later the liver dulness dropped to the sixth space, and as the toxemia passed off it dropped to the normal level. One might believe that the diaphragm muscles had a tonus with the heart tonus, which, as the relaxation increased, would be gradually expanded. Perhaps the lung dropping down would be diaphragmatic tonus.

Carbohydrate-fat Ratio in Reference to the Production of Ketone Bodied Diabetes.—Dr. W. W. PALMER of New York and (by invitation) Dr. W. S. LADD, presented this paper. He said that studies had been made to determine a sufficient diet in diabetics which would maintain nitrogen equilibrium. High carbohydrate was started with low fat, and later the carbohydrate was lowered and fat increased. The patients maintained weight during the experiment. The limits of carbo-hydrate-fat ratio in diabetes were studied. If one figured that one-half of the amount of protein should be carbohydrate, this was added to the carbohydrate amount, so that one kept within the one-to-four ratio to be on the safe side. There was probably a relation between glucose in the diet and the fatty acid. It might require one triose molecule to oxidize one *B*-oxybutyric, so that when one calculated the total available carbohydrates it seemed probable that one molecule of glucose had been oxidized instead of one of triose. In the test tube, aceto-acetic acid oxidized very slowly, but when glucose was added it oxidized rapidly.

Objects and Method of Diet Adjustment in Diabetes.—Dr. R. T. WOODYATT of Chicago made this presentation. He said that in spite of the work of Allen and Joslin, there were many varied opinions as to diabetic diets. In some cases the strictly limited diets gave good results. One characteristic of diabetes *per se* was inability to use glucose in excess of a certain amount. The pancreatic secretion was altered in this respect. The quantity of food which might be normally oxidized by the body was determined by the quantity of glucose which was oxidized. Therefore one must bring glucose within the limits of the body's power. In a fasting state the body used endogenous supplies for its nutrition; even on a maintenance diet, endogenous food was used. There were thousands of combinations of fat, protein, and carbohydrate, but all carbohydrate must become glucose before it could be oxidized. One hundred grams of protein would yield 58 per cent. glucose, and 100 grams of fat would yield 10 per cent. glucose; and in giving these elements one must watch for the critical point at which acetone appeared. One must adjust carbohydrate to the highest possible level, because it would carry more fat than protein would, and therefore spared protein. If one added protein one must remember to subtract calories. The addition of fat reduced the quantity of glucose going into the metabolism. Cream was very useful in this respect, and spared protein.

Dr. L. N. NEWBURG of Ann Arbor, Mich., said that this work was another step away from the forced starvation diet. From the clinical point of view he believed it was wrong to subject the diabetic to the prolonged effect of under-nutrition. He had tried to devise a diet which would not produce under-nutrition, and would prevent glycosuria and acidosis. He found he could do this with the addition of large amounts of fat to the diet. Dr. Woodyatt, working from another angle, had arrived at the same conclusion. He had worked out the optimum diet on the basis of the lines of metabolism, using the metabolic expression of the optimum diet as it should be fed to the diabetic. With this method he had arrived at a diet high in fat. Treatment would be advanced as soon as proven that this method was of use in diet.

Dr. E. P. JOSLIN of Boston said that there was more in Dr. Woodyatt's paper than one could appreciate to-day. He had spent several hours upon it and was impressed with it. His general attitude toward the matter was this: What Dr. Allen did for earlier work Dr. Woodyatt had done for Dr. Newburg's work. In regard to Dr. Allen's work with under-nutrition, before that was inaugurated, many children lived one year and died. That was before 1914. The next series treated by the method since 1914 had lived over two or three years, whereas in adults before 1914 the average duration of life was three years; since that period cases had lasted for five years. This represented all the cases. One could now give a seven-year prognosis for 100 diabetics coming for treatment. Therefore, as the result of the 1914 methods, an extension of life of cases had actually taken place. Now perhaps they could look forward to another improvement by utilizing some of the ideas brought out by Dr. Newburg, and elaborated and expanded by Dr. Woodyatt. What should be the attitude of the doctor of today to this new idea? Should one go over to the new method of treatment and increase the quantity of fat in the diet? Dr. Newburg's cases became sugar and acetone-free in the treatment. Dr. Joslin had tried this treatment in the worst possible cases of diabetes, who were not doing well under care. As a result, in these four cases, none became sugar-free, none became free from acidosis. In one, acidosis became so severe that coma threatened. The alveolar air had dropped to 14 mm. mercury. That did not mean that Dr. Newburg's treatment should not be utilized. One could use it in selected cases. These four patients felt that they deserved to know the results in Dr. Newburg's 69 cases. There was some trouble in tracing the cases. The statistics were these: Twenty-two were traced; eight were dead. The question now arose, what should he do with two boys, with diabetes beginning at the age of 12, but at the end of three or four years of treatment by the old method they had a carbohydrate tolerance of 100, protein 17. Should he put these boys on lower protein and push up their fat, or should he continue by these methods which had hitherto helped them for three or four years. He felt that one should hesitate to adopt new methods. Perhaps there was a maximum amount of fat that one could give, perhaps 75 per cent. One must be positive not to lose the advantage of the last six years and the patient's chance of duration of life.

Dr. F. M. ALLEN of New York said he must speak at random in regard to Dr. Palmer's paper, and the subject of fat and carbohydrate metabolism. One must effect a balance of three factors: carbohydrate, fat, and the organism. If one considered the organism, these conditions were fulfilled under fixed conditions. The total quantity of the diet was one factor, and the ratio affected this. Very thin, emaciated patients might never have an acidosis, no matter how much fat one gave, but in a well-nourished individual one ran the risk of a serious acidosis. It was a question whether the ratio would hold. Under-nourished people did handle protein as if it were carbohydrate and would remain ketone free. That did not hold with over-nourished people. Perhaps it was not possible to over-nourish without ketonuria, or keep the patient ketone-free on a luxus diet. Reactions of the organism differed, and different types responded differently. Even in normal individuals there were variations in fat tolerance. The experiments of Higgs, Reading, and Fitz were made with feeding and respiration tests. The individuals had identical intakes and reacted differently in the amount of ketones produced. Age was another factor; an adult dog could pass to death without

acetone, while a young puppy might show fatal acidosis. In experiments on human subjects at the Rockefeller Institute he tried to trace the cause; he obtained definite evidence of internal secretion influence. This was a serious matter, because fat added to the diet might make the diet excessive. Carbohydrate might be tolerated with little fat, but not with high fat. This had been proved by experimental clinical evidence. Two patients were alive to-day with unimpaired tolerance, and one had lowered tolerance because she stole the butter. One can give enough sugars in the form of food, liberal in proportion, but one must measure the total caloric intake. If one made that too high, the patient would die. If one kept the patient sufficiently under-nourished one would abolish downward progress. They had young patients undergoing this treatment who continued without decline of tolerance, and progressed better than on high diet, which was impossible in this type of diabetes.

Dr. S. STRAUSS of Chicago said that in the last few years excellent results had been reported in diabetes, due as much to the care and skill of the physician as to the particular form of diet. There were two classes of diabetics who did not respond to under-nutrition: those who despite rigid adherence to low diet, did not retain the balance and the older, chronic diabetic, who when he had sugars did not feel well and was much more apt to develop symptoms. Patients did not follow diets strictly. That had to be met. There was a difference between malnutrition and a luxus diet. There was the moderate diet which contained more fat than they had been accustomed to using.

Dr. W. W. PALMER, in closing, said that as Dr. Allen said, patients varied. In cases which one considered satisfactory, as one approached 10 per cent. carbohydrate, when first making the shift there was a temporary increase of acetone bodies, then the body adjusted itself to the diet. If one made a further shift, then the increase in acetone became constant. In adding fat one was adding glucose in the glycerol fraction. Dr. Woodyatt had pointed out certain fundamental facts in the treatment of these cases.

Dr. R. T. WOODYATT, in closing, said Dr. Joslin's comments were entirely sound. Every individual should not be put on the optimum diet. That should be left to the judgment of the clinician. Where nutrition was the first question one might be able to get 1800 calories, and this method might help in doing so. All of this more accurate work had been developed as a result of the stimulus given by the work of Drs. Joslin and Allen, and the improvement in the average results had come from them. Dr. Allen's remarks were covered by the original three statements. One must consider the glucose, and stop dealing with three variables, which was impossible without confusion.

Familial Diabetes.—Dr. H. R. M. LANDIS of Philadelphia presented this study. He said that there was a certain hereditary tendency in diabetes, but familial diabetes was not common. In the family studied there were ten children in the family, nine living. There were four blonds, free from symptoms and five brunettes, who all had glycosuria. The patient seen was an intelligent woman, who had applied for life insurance, and was rejected on account of sugar in the urine. The next sister had had failing health for some months, and was found to have much sugar. This tendency seemed to have skipped one generation, and to have appeared in grandchildren. There seemed to have been a distinct hereditary and familial tendency in this case.

Dr. S. SOLIS-COHEN of Philadelphia said that this confirmed in some measure speculations on the subject of tuberculosis, carcinoma, and diabetes and endocrine disturbance, which he had put in the Osler volume. He reported three clans, consisting of a number of families, in some to the fourth or fifth generation, in which were found distinct antagonism between tuberculosis and carcinoma, on the one hand, and diabetes on the other. Those who escaped tuberculosis and carcinoma usually showing marked endocrine disturbance with symptoms of diabetes. Among sixty-five diabetics one showed tuberculosis. Analysis of large statistics would bear out the same proportion with tuberculosis and diabetes, which were really manifestations of antagonistic tendencies.

Dr. J. M. ANDERS of Philadelphia said he had been interested in the subject of familial diabetes. It was supposed to occur in obese subjects. His rather extended experience in the treatment of obesity confirmed this view. He had the definite impression that in those cases of familial diabetes occurring in obese subjects gout figured as the cause of the obesity. The manifestations occurred in late life and were not severe, but if in early life they were severe. Von Norden had shown close connection between obesity and diabetes. Gout was in the same group. Obesity and gout were hereditary and in both there was marked tendency to glycosuria. This partly explained familial diabetes.

Dr. F. M. ALLEN of New York said that this was an interesting attempt to determine how and why tendencies were inherited and whether disease characters followed Mendelian laws. One should make glucose-tolerance tests of the non-diabetic members of these families to determine whether or not there was a diabetic tendency.

Further Observations on the Blood Sugar Tolerance Test as an Aid in the Diagnosis of Gastrointestinal Carcinoma.—Drs. JULIUS FRIEDENWALD and G. H. GROVE of Baltimore presented this communication. Previous studies had established that the curve of sugar tolerance was different from that of carcinoma of other parts of the body. It was rather distinctive, so that it might render differential diagnosis between carcinoma and other disease of the gastrointestinal tract. Examination of curves showed: (1) Normal curve, two hours after 100 grams glucose, fell to normal; (2) atypical normal curve (achylia gastrica) fell slowly after two hours; (3) intermediate curve, blood sugar high, associated with carcinoma of other parts of the body; (4) gastric carcinoma curve high blood sugar. Forty-six cases had been studied since the original communication. The results showed that cancer curves could be distinguished from cancer of other parts of the body. Tabes, nephritis, tuberculosis, thyroid conditions should be excluded, as hyperglycemia was often present in these conditions. The test had proved positive in 72 out of 75 cases studied, and was therefore a valuable diagnostic measure. It was positive in five non-malignant cases but it was sufficiently specific to be taken into consideration with other points of diagnosis.

The Relation of Acromegaly to Thyroid Disease, with a Statistical Study.—Dr. JAMES M. ANDERS of Philadelphia presented this study. He said that it was generally accepted that hypoactivity of the anterior hypophysis occurred after union had taken place. He believed that perversion of secretion, rather than excess, was the rule. Usually there was dilatation of the sella, with persistent thymus. Neoplasms were of various kinds, adenoma sarcoma, cystic degeneration, etc. Sometimes the hypophysis was normal in every respect, so that disturbance might occur without any microscopic or macroscopic lesions. These were ductless gland neuroses and were rather rare. There might also be hypertrophic enlargement or even destructive lesions, without acromegaly. Removal of the thyroid was followed by hypophyseal enlargement, also in hyperthyroidism there was enlargement of the hypophysis, so that it appeared that the glands could function by compensation up to a certain point. There was also a certain clinical connection between myxedema and hypophyseal disease. The anterior hypophysis was supplied by sympathetic nerve fibers, while the posterior was not, and this sympathetic innervation would explain the influence of the thyroid gland. They found five of sixteen cases with associated thyroid disturbance: one hyper and four hypo cases. They should apply the sugar tolerance tests and estimate the metabolic rate, which had not always been done. In 215 acromegalic cases, 91 had thyroid lesions; the average was 32, and females were slightly in excess; glycosuria was present in 35 per cent. The pituitary disturbance appeared to precede the thyroid disturbance by several years.

The Blood in Tetrachlorethane Poisoning.—Drs. GEORGE R. MINOT and Dr. L. W. SMITH of Boston presented this topic. Minot said this chemical could produce serious or fatal hepatitis. Industrially it was used for airplane burnishing, for films, and in artificial silk. The poison acted particularly on the blood

and on the liver. The symptoms were very ill defined. The person was fatigued, had slight gastrointestinal symptoms, constipation, perhaps jaundice. The liver was palpable and tender. The onset was insidious. Of 68 persons exposed 21 had poisoning. There was a definite blood picture. There was progressive increase of the large mononuclears, reaching as high as 40 per cent. There was a slight secondary anemia. The blood picture could be discovered before symptoms appeared. Respiratory affections seemed to lower the resistance of the workers. When there were blood changes and symptoms, this indicated removal from work. Recovery was gradual. Persons who had once been affected were more sensitive to the poison in future.

A Method for the Study of Early Arterial Changes.—Dr. HARLOW BROOKS of New York presented this topic. He said that the diagnosis should be made early, and this was impossible except on two grounds: suspicion of trouble, and examination of the retinal vessels. The latter was difficult for those inexperienced in ophthalmoscopic methods. Examination of the conjunctival vessels was much easier, as these vessels represented the intracerebral circulation. They appeared bluish white on the background. The eye must be near the lens, and the examination only took a few minutes. If one had the corneal microscope, technical skill was required, but the work was very fascinating. One could see the anatomical and physiological changes. The changes appeared very early in hypertension, even when transitory. The vessels looked like cords. There were often zones of obliteration and formation of small saccular aneurysms. These were very striking.

Dr. S. B. WOLBACH of Boston asked what the caliber of these vessels was. Dr. Brooks said that some were very narrow, some very broad. The size varied as much as did that of the radial artery, but one would not have any difficulty in distinguishing pathological vessels.

Further Study of the Estimation of Quantitative Variations in the Vibration Sensation.—Dr. E. J. WOOD of Wilmington, N. C., presented this communication. This work was begun at Guy's Hospital, as a continuation of Sims' work. The vibration sensation was first studied in the Gradinego triad. An attempt was made to make clinical application of vibration in routine neurology. The instrument used was introduced by the aurists in England. The prongs of the instrument were separated when a sharp blow was struck. Normal range was studied in 100 people without neurological conditions. Tabes was then studied and a diminution in the vibratory response over the sacrum was found. Tests were made over the internal malleolus, external malleolus, tibia sacrum, and sternum. This sacral diminution in tabes appeared before Argyll-Robertson pupils were evident. Dr. Henry Head suggested that there would be definite relationship found between this test and serological findings, and that this would be of earlier diagnostic import, and would do away with the necessity of frequent lumbar punctures. This was more than they were prepared to say at present.

Pituitary Extract and Water Balance.—Drs. L. G ROWNTREE, E. E. LARSEN, and J. F. WEIS of Minneapolis presented this paper. Water balance and water intoxication were studied in fifteen cases of diabetes insipidus. There was increase of thirst, polyuria, and polydipsia. Studies were made to determine whether thirst was the primary symptom. In some cases thirst preceded polyuria. Pilocarpine did not relieve the thirst, neither did cocainization of the mucous membrane. Pituitary extract had no effect on water excretion, neither had a spinal puncture. The blood showed increase in plasma, volume, and molecular constituents. It was thought there was hydremic plethora with increased renal threshold. In dogs with water intoxication very violent symptoms were shown, convulsions, and frothing, but the animal recovered in a few days. Simply forcing water led to water intoxication. There was no evidence of edema of the brain.

Dr. D. I. MACHT of Baltimore asked if in the clinical cases any spasm of the urinary bladder was noted. It was stated that the urinary bladder was more sensitive than the uterus to the action of pituitary extract. It would be interesting to note this.

Dr. HARLOW BROOKS of New York asked if there were any changes in temperature.

Dr. ROWNTREE said there were no changes in temperature, either in the animals or the clinical cases. As to spasm of the bladder, one wondered whether it was smooth muscle contraction. They got the effect when there was a catheter in place, so there was no real effect on the smooth muscle. He did not know whether there was contraction of the bladder.

Therapeutic Hints.

Cade Oil Baths.—The following formula for an emulsion of oil of cade for baths is used in the Hôpital Saint-Louis, Paris:

Oil of cade.	
Soft soap.....of each,	50
Soap bark (concentrated decoction),	10
Water, ...to	250

Cade ointment, as used at Hôpital Broca, Paris, is made by the following formula:

Oil of cade.....	30
White wax.....	10

The white wax is slowly dissolved in the cade oil, the mixture being stirred until cold.

—*Journal des Praticiens.*

Galvanic Current in Idiopathic Priapism.—A man of twenty-eight, apparently in perfect health, entered a neurological clinic seeking relief from persistent priapism. Various sedative agents, including chloroform anesthesia, proved ineffective. After twenty-eight days the galvanic current was applied, the condition slowly yielding, and subsiding completely after eight days.—*Brazil Medico.*

Abortive Treatment of Gonorrhea.—Boyer recommends the following solutions, to be used first, to bring about a profuse exudation, which carries with it the gonococci, to exert a powerful antiseptic action, the treatment to be begun not later than the third day of the discharge.

1. Collargol	1.50
Glycerin	30.0
Distilled water	250.0
2. Permanganate of potash.....	10
Distilled water	300

The patient, after micturating on rising in the morning, injects into the urethra 10 c.c. of the first solution, using a small glass syringe, and keeping the meatus closed by means of the left thumb and forefinger. After holding the fluid in the urethra for four or five minutes, the excess is allowed to run out and a small plug of cotton wool applied. At noon, after urinating, the patient washes out the urethra with a dozen syringefuls of the second solution, retaining the last syringeful for from four to five minutes. Another injection of the first solution is given at two o'clock, and at 7 o'clock the urethra is washed out with the second solution. The discharge is generally found to be free from gonococci after the third day, and from the sixth to the eighth day the discharge ceases.—*Journal des Praticiens.*

Fermentative Dyspepsia.—Brose Horne gives the following as affording the surest relief he has obtained:

Phenol iodine	1/8 gr.
Sodium salicylate	1 gr.
Guaiacol	1/4 gr.
Oil of cloves.....	1/2 min.

M. to make one tablet. Sig.—1 to 3 such tablets after meals.—*Medical Summary.*

Miscellany.

NEW BOOKS AND OLD.

X. DR. STREETER'S EXHIBITION AT BOSTON.

By JOHN RUHRÄH, M.D.

BALTIMORE, MD.

DURING the meeting of the American Medical Association Dr. Edward C. Streeter had on view, in the exhibition room of the Boston Public Library, a selection of early medical texts illustrating the history of the specific infections and epidemic diseases from Hippocrates to Sydenham. The exhibit was arranged chronologically for the most part, although this was not followed strictly, as a considerable amount of material was introduced illustrating the history of plague, syphilis, and venesection. In addition to the books Dr. Streeter also showed a series of photographs and illustrations dealing with the history of infections and also a series of photographs of paintings showing the chemical laboratories, or perhaps one should say the laboratories of the alchemists of other days.

Of particular interest were the illustrations of the Saints of healing, Cosmo, Damien, Roche, and others, and the occurrence of plague and syphilis in art. The costumes of plague doctors and their aides and the broadsides used in quarantine and in plague times formed another important part of the exhibition.

The exhibit of early medical texts naturally began with the Omnia Opera Hippocratis in a beautiful first edition of the Greek text printed in 1526. Then followed a seriës of well known names and some less familiar, including Galen, Aetius of Amida, Paulus Aegineta, Rhazes, Avicenna, and others including a first edition of Gilbertus Anglicus and also a first edition of a poem by Gilles de Corbeil, and nine different editions of the Regimen Sanitatis Salernitanum, which poem was first printed in Paris in 1497. The first edition contains the commentary of Arnaldus de Villanova. There was also a copy of Roland of Parma's work on the cure of plague buboes. Roland was one of the surgeons mentioned at the School of Salernum who with Roger of Salerno is said by Allbutt "to stand like twin brethern in the dawn of modern medicine, bearing the very names of romance."

It would certainly be a dull physician who would pass by the first edition of John of Gaddesden's *Rosa anglica*, first printed in 1492, or the beautiful English medical manuscript of the great *Chirurgie* of Guy de Chauliac. According to the note in the catalog Quaritch regards this as the finest English medical manuscript in existence. It is a beautiful piece of work in Middle English script, beginning "Here bigyneth the Inventorie or the Collectorye in cirurgicale parte of medicene." The work is on vellum, 13 by 9 inches, double columns, with 48 lines to a page, ruled in red, with red rubrics and headlines, with twelve pages of full or half floriated borders and twenty-four drawings of surgical instruments. Streeter had it opened at Book II., Chapter 5, "Of ye grete pestilence," which dealt with the plagues of 1348 and 1360.

Among the other plague items was a copy of the first medical book printed in England in a facsimile copy of that in the John Rylands library. This is an English version of a "*Tractatus contra pestilentiam*" ascribed to Johannis Jacobi, of Montpellier, whose date is given as 1373. The book itself was printed at London by William de Machlinia in 1485 and is entitled "A litil Boke the whiche traytied and reherced many gode thinges necessaries for the infirmite and grete sekenesse called Pestilence."

Perhaps the rarest book in the collection was the "Traicte des Urines," printed in French about 1530 and sold in Paris at the Rue neufe Nostre dame a lenseigne Sainct Nicolas. This is apparently a unique item, Dr. Streeter owning the only known copy. In his catalog of the books he reproduces the first page of this and also the first page of a rare Spanish imprint unknown to bibliographers, by Louis Lobera de Avila, who was physician to Charles V. It is entitled *Libro de Pestilencia*. There is also a German translation of the same work dated 1531.

There was a reprint of John Caius' book on the sweating sickness and also a copy of Medicina by Joannes Fernelius, who also described the outbreak of sweating sickness in England.

In the books on syphilis there were quite a number of rare works, among which I noted the rare first edition of Nicolaus Leonicenus; also the first edition of the famous poem of Fracastorius entitled *Syphilis sive Morbus Gallicus*, printed at Verona in 1520.

There were quite a number of interesting plague items, including the work of Ballonius, the influential Dean of the Paris Faculty in 1580, when the plague was devastating France. I was particularly interested in a volume containing a number of works on the plague, two of which were by Thomas Thayre. These are of especial note inasmuch as the name is so much like that of Thomas Phaer or Phayer, whose book on the Pestilence is in most editions bound up with his translation of the Regimen Sanitatis Salernum. Phaer also translated Virgil's Aeneid into English. Thayre was a seventeenth century physician in London, held in no high esteem. After the manner of many writers of medical books he appropriated much of the material collected by others. He used the work of Phaer without giving that author any credit. Anyone interested in Phaer will find a complete account of him in a recent number of the Annals of Medical History. He is of particular interest to those working in pediatrics, inasmuch as he wrote the first English book on the diseases of children.

The collection ended with a copy of John Pringle's "A rational inquiry into the nature of the Plague," printed in London in 1722.

Dr. Streeter cannot be given too much praise for affording the medical profession and also the medical librarians whose association met in Boston an opportunity of seeing such a wonderful collection so well arranged and so satisfactorily catalogued.

It may not be out of place to call attention to the fact that Boston has started a society for the study of medical history, with a rather large membership, under the presidency of Dr. Harvey Cushing, with Dr. Streeter as secretary. All workers in medical history will join me in wishing this new organization a long and useful career.

Italian Physicians in Old France.—Di Pace calls attention to this subject in *Il Policlinico* for April 25, 1921, xxviii, 17. The earliest record of the settlement of Italian practitioners in French territory was in connection with graduates of the famous School of Salerno. Some of these appear to have practised astrology and may be passed over for later arrivals. After the School of Salerno had lost some of its renown and the School of Sienna had become well known some of the alumni of the latter attained eminence as practitioners in France. One of these—Aldibrandino—was summoned to the latter country on a medical errand. He was the first of his nationality to write a medical work in the French language. This was a book on hygiene, composed at the request of his patroness, Beatrice of Savoy, who had brought him on. Later he was summoned to Paris to treat King Louis IX. The latter, known to history as St. Louis, liked Italian practitioners so well that he summoned to him later William of Cremona and Nicholas di Calvopetro. It was about thirty years later that Lanfranc of Milan, the celebrated surgeon of the Middle Ages, while wandering from place to place in the search for recognition stumbled upon Paris, where he realized on his reputation a hundred-fold more than he deserved—to use his own expression. It sounded like a modest man, but Lanfranc was anything but modest. His misfortunes had been due originally to having taken part in politics, on what chanced to be the losing side; which defeat led to his exile. When things started to come his way in Paris he took occasion to stigmatize the combined surgeons of the metropolis as ignoramuses. In order to make good he set to work and wrote his celebrated treatise on surgery, which went through many editions and translations.

The success of Lanfranc was so remarkable that many Italians followed him to Paris. Thaddeus of Bologna, Lodovico, of Reggio, Ugo of Lucca, Nicholas of Florence, Augustus of Verona, Ruggero of Salerno, Silvester of Pistoia, Valescus of Tarentum, Lodovico of Pisa, Bruno of Calabria, and Armando of Cremona, all hied to Paris, representing in that city nearly every region of Italy. Naturally there was much jealously among the new arrivals, to say nothing of the feelings of the old Parisians. Pitard, then physician to St. Louis, solved the problem in part by founding the society of surgeons known as the "Confraternity of St. Cosmo." Later there arrived a practitioner from Constantinople, who had studied Greek and Arabic medicine in its original home. He was Pietro di Albano, and he acquired reclame by announcing that medicine, astrology, and magic must be studied jointly to turn out a first-class practitioner. The Parisians "fell hard" for this sort of boosting, and Pietro got his 50 scudi per consultation. The Pope sent for him professionally, his honorarium being 400 ducats a day. But his swath was so wide and he made so many enemies that his fame was turned to his discredit by crediting the devil with his cures; so that in the year 1312 he was up before the Inquisition. He died soon after—possibly was done to death—and was burned in effigy. Ruggiero di Parma later obtained some fame in Paris for improvements in the care of the insane. In the next century Queen Joan of Bourgogne had as her personal physician Guido of Vigevago, who distinguished himself by writing a treatise on military hygiene. Torregiano of Florence published his commentary on Galen, which was a good medieval way to obtain publicity, and managed to convey the impression that he was rather more than a mere commentator. Space does not serve to give mention of all the Italians enumerated by di Pace. Valescus of Tarentum was famous as author, practitioner, and court physician and his treatise on medicine, written after thirty-six years of practice, is one of the best of its kind. Finally in 1654 there arrived Botallus of Asti, who was also court physician and author of a treatise of medicine. Even as early as the time of Louis XIV more than 200 Italian physicians had been prominent in the medical affairs of Paris.

The Influenza Epidemic in Austria in 1920.—Schiffner and Spengler have studied this epidemic with the aim of comparing it with all previous visitations (*Weiner klinische Wochenschrift*). Thus far the Pfeiffer bacillus has been consistently absent and the organisms chiefly found were staphylococci and pneumococci. The disease still spreads from person to person as the chief method. The elderly still have a natural or active immunity. In all of these respects the recent epidemics differ from those of 1890 and following years. Of recent years many have been twice attacked by influenza, thus showing absence of acquired immunity. Clinically the disease begins, as heretofore, as a catarrhal fever. The menses sometimes come on prematurely. In the hospital wards uncomplicated grippe was rare, for save in about 13 per cent. pneumonic complications were present on admission. The peculiar double fever curve with an intermission seen so commonly in 1918 was almost entirely absent. Grippe pneumonia is essentially lobular now, with frankly hemorrhagic sputum, and the croupous pneumonia of the pandemic is less common. There is no massive area of consolidation but whispering bronchophony is almost always present. Albuminuria is still almost constant. This epidemic is perhaps most conspicuous for its neurotropic tendency, regardless of the doubtful connection between grippe and encephalitis lethargica.

In regard to treatment, convalescent serum and antipneumostreptococcus serum appear to give encouraging results. A chemotherapeutic remedy devised by Morgenroth is said to have some power in preventing complications. The formula is not given. The unknown substance is given chiefly with one of the antisera. In addition to those already mentioned diphtheria serum and normal horse serum are enumerated. Among drugs strychnine and caffeine are injected subcutaneously or intravenously and digitalis is given *per os*. The authors treated a series of 60 cases of which 52 were lobular pneumonias; of these 42 are cured and 7 others under treatment or convalescent, while 11 are dead, all but 2 of pneumonia. The percentage of pneumonia deaths is therefore 17 which would have been remarkably low during the pandemic. The authors, however, by grouping the figures in such a manner as to eliminate accident make the percentage of fatalities 10 for grippe and 11.5 for pneumonia.

THE THYROID.*

BY CHARLES H. MAYO, M.D.

ROCHESTER, MINN.

THE great progress made in medicine during the past few decades has come about largely through studies in biology and physiologic chemistry. The changes demonstrated by physiologic chemistry are due to the activity of cells; the chemists have proved that these changes are caused by definite electron reactions. We were once content to learn of new remedies and to know that certain diseases are affected by certain drugs, as for instance the action of digitalis on the heart muscle; but later the question came up of why digitalis should have a selective action on the heart muscle. The answer was, "Because of its chemistry." It has been found that bacteria have a selective action, and the question of why this is so arose. Why does the microbe of anterior poliomyelitis locate in the anterior horns of spinal ganglia? Again the question was a chemical one involving the chemical constituents of the ganglion cells.

Another interesting study is that of the chemistry of irritation and inflammation, whether it is the result of the action of plant cells as drugs, or is produced by microbes, and whether the effects are local or are carried by chemical products to various parts of the body. For example, in the use of Dakin's solution a combination occurs between the cells of certain tissues and the substances in the solution. The reactions involved in the use of Dakin's solution were investigated by Mann in order to determine the toxic limits of the solution. He found that more than 12 c.c. for each kilogram of body weight administered intravenously is a lethal dose. It is interesting that from 5 to 10 c.c. for each kilogram of body weight does not cause sickness, nothing beyond changes in the wall of the gallbladder being found in the necropsied animals. By such intravenous injections the gallbladder circulation was temporarily blocked, and the lymphatic system showed involvement. Lipoid changes were found in the mucous membrane. There were inflammatory changes, and at times slow changes resulting in a varying degree of destruction of the gallbladder wall by repeated doses, but the action was shown to be chemical.

Kendall, after six or seven years' work, has been able to produce thyroxin synthetically. In his work he used three and one-half tons of the thyroid glands of pigs; he was finally able to express in chemical terms the material of the secretion of the thyroid. The clinical work of Plummer and the metabolic work of Boothby, based on Kendall's studies, permitted the completion of these investigations. They were enabled to determine the amount of thyroid secretion in an average gland and in an average body, and the length of time that the amount in the body would functionate after the removal of the gland. Similar procedures might be carried out on other glands and in other diseases. These observers had an almost unparalleled opportunity for study because of the vast amount of material in the clinic. Kocher, at the time of his death, had performed in his clinic about five thousand operations on the thyroid. At Rochester there were five times as many, twenty-five thousand thyroids having been operated on or treated medically when operative procedure was inadvisable.

There is a tremendous amount of goiter in this country. Comparatively few of the cases occur in New England or in the Southern States. There were about three cases of goiter to each 1000 of draft recruits in the district of New York, seven cases to 1000 in the Great Lakes region, eight or nine cases to 1000 in Montana, and fourteen cases to 1000 in Oregon, Washington, and Idaho. The incidence of exophthalmic goiter, three to 1000, as noted by some Western Draft Boards of the Army, is too high for men in the third decade, since most exophthalmic goiters occur in women.

In Europe a condition resembling exophthalmic goiter was recognized and designated pseudo-Graves' disease, Basedowized goiter, or *formes frustes;* in this country this type of goiter was not clinically distinguished until recognized by Plummer in 1909. He showed that there is a group of patients with long-standing goiter, perhaps of fourteen to twenty years' duration, not accompanied by exophthalmos, but with hyperthyroidism. The iodine content in the thyroids of such patients is variable.

The thyroid gland is one of the most important glands in the body, being protected by a circulation greater than that of any other gland. Nature has provided every safeguard that no loss of circulation should possibly occur. On the other hand, the lymphatic supply of the thyroid is not good. Structurally the thyroid consists of a mass of encapsulated alveoli held together by a stroma of connective tissue; the vesicles are lined by a single layer of cells which normally hold some colloid and may collect more. So far as is known

*Abstract of paper read at a meeting of the New York Academy of Medicine, April 7, 1921.

the secretion in the interior of the vesicle can escape only by passing back through the cells which produce it. In exophthalmic goiter there is an hypertrophy of the epithelium causing crowding of the vesicles and no retention of secretion. In simple goiter and in the goiter of adolescence an excessive amount of the colloid is retained. A possible theory is that a portion of the gland is not working and that the remainder is carrying on the function which the entire gland would ordinarily perform.

All cystic goiters are the result of degeneration following failure of the blood supply of encapsulated adenoma. The cystic goiter is encapsulated and thus the thyroid is converted into an extra capsule. Destruction of the gland due to disease produces hypothyroidism; a few such cases are the result of too radical operation. Undoubtedly a large number of patients with exophthalmic goiter improves without treatment. Removal of the sympathetic cervical ganglia, both superior and middle, was attempted with a view to overcoming the excessive stimulation, but enough relief was not obtained to warrant the operation. It occasionally reduces apparent exophthalmos by dropping the upper lid. In ligations the nerve, the vein, and the artery are included. Patients with adenoma should be operated on. Some soft goiters in young persons respond to treatment. As soon as treatment is commenced, the gland ceases to function just to the extent that the medication supplants its work, and it diminishes in size so rapidly that its decrease can be measured.

The soft goiters of adolescence respond to treatment with sodium iodide and thyroid extract, although the treatment required may sometimes be prolonged. In this connection the experimental work of Marine may be mentioned. In Akron, Ohio, Marine administered small doses of sodium iodide to three thousand school girls in a certain area. He found that fewer among this group developed changes in the thyroid than among a similar group to whom no treatment was given. Simple goiters are not uncommon in young persons. Later in life nodular encapsulated adenoma may develop on fetal tissue with colloid, or there may be various degrees of calcareous and fibroid changes; a cystic degeneration is rarely toxic.

In cases of toxic adenoma producing hyperthyroidism, the average age at which the hyperthyroidism makes its appearance is forty-three years, while the average age at which these patients are operated on is forty-eight years. In patients with exophthalmic goiter the average age at which the hyperthyroidism manifests itself is from thirty-one to thirty-six years; exophthalmos appeared in about 50 per cent. of these patients within a few months after the onset of symptoms. I have seen children under ten with typical symptoms of exophthalmic goiter, such as tremor, tachycardia, nervousness, and exophthalmos. A number of cases of thyroiditis and tuberculosis of the thyroid have been observed in the clinic. Goiter probably never wholly destroys the functions of the gland, producing myxedema, but they might be destroyed by thyroiditis. A small, hard, symmetric gland, not exophthalmic goiter, may be tuberculous. Thyroiditis and carcinoma in the early stages are similar in appearance. Carcinoma of the thyroid rarely produces symptoms early in the course of the disease. If there are irregular, hard nodules in the gland it is probably malignant, especially if the adjacent lymphatics are enlarged, but exploration with examination of tissue is necessary for diagnosis.

The epinephrin test may produce dangerous reactions and in a large percentage of cases might lead to wrong conclusions. Many psychoneurotic patients would be placed with the group of patients having exophthalmic goiter on the basis of the epinephrin test. On the other hand, a failure in diagnosis is almost impossible if the basal metabolic rate is taken into consideration with other general symptoms. Patients with simple goiters occasionally have slightly low metabolic rates of —8 to —10, but as a rule the basal metabolic rate must be lower before definite symptoms of hyperthyroidism are manifest, as in myxedema. The edema of myxedema in primary hypothyroidism appears quite definitely as soon as the basal metabolic rate falls below — 16 or — 17. In the treatment of myxedema by thyroxin the appearance and disappearance of the edema can be noted from variations of three points in the basal metabolic rate around —17 and in a period as short as three days. The statement that the removal of thyroid tissue may be extensive and complete without producing myxedema and symptoms of thyroid insufficiency is not supported by the metabolic rate tests on patients after radical or nearly complete removal of the gland.

Substernal goiter is more common than was supposed. Sometimes its presence is indicated by the veins on the neck extending down over the chest, showing the obstruction to the venous flow. This type of goiter is frequently well encapsulated and can be easily enucleated, especially if the patient cooperates by a little cough. In order to have the advantage of the cooperation of the patient, operations on goiters of this type should be performed under local anesthesia.

Syphilitic goiter is not very common, and sarcoma is rarer than carcinoma. A group of over 200 patients with malignant tumors of the thyroid has been operated on at the Mayo Clinic, and in addition the condition of nearly a hundred patients examined was found to be hopeless and operation was not advised.

Treatment with the *x*-ray and radium has been used in our clinic to some extent. The *x*-ray produces so much connective tissue that the gland will require knife section if operation becomes necessary. The *x*-ray probably has a beneficial effect on the thyroid and might give relief for a period of time; however, a certain number recover, anyway, without treatment. Such severe scarring has followed *x*-ray treatment in a number of cases that the patients were willing to submit to a skin grafting or any other procedure that promised to remove the scar. The *x*-ray is also dangerous in that it might produce a complete destruction of the gland; one patient came to the clinic with cancer of the skin over the gland caused by long *x*-ray treatment.

About twenty years ago surgeons did not see patients with exophthalmic goiter in the early

stage; patients who could be cured medically did not consult a surgeon. Because of lack of knowledge, surgery was not advised for these patients until late in the course of the disease. Thus we had the vicious circle of late operation and high mortality conducing to late operation. As the surgeon came to be sought earlier the risks of operation decreased. Under the unfavorable conditions of late operation the mortality had been from 15 to 20 per cent. Recently as many as 146 operations have been performed at the clinic between deaths. Patients with exophthalmic goiter pass through exacerbations of symptoms which are largely influenced by psychic stimuli and are easily exhausted. At this period the patients should be treated medically, not surgically. If necessary, ligation, *x*-ray treatment, and hot water injections may be given in conjunction with absolute rest. Rarely the hot water, not hot enough, probably made the condition worse by diluting the secretion; the water should be boiling. The injection of quinine urea has not proved of sufficient benefit to be worth while.

A basal metabolic rate as high as + 85 to + 100 may fall to + 35 or + 40 if the patient is placed under rest and treatment; this may, however, be but a fictitious improvement. A patient with a metabolic rate of + 56, who has survived a recent exacerbation and is improving, is a safer risk than a patient with a rate of + 46 who is on the rising wave of an exacerbation. Ligation should be performed under local or nitrous oxide anesthesia. Most patients can be operated on under local anesthesia.

With modern technic and methods, the mortality in exophthalmic goiter has greatly decreased, probably due more to early operation than to the advances in surgery.

In operating on a patient with a large goiter a transverse incision should be made through the skin and platysma and in the line of the folds in the skin of the neck. The trachea is then exposed, but should not be dissected too freely or congestion and temporary loss of voice or hoarseness will follow on the second day, with recovery later. A primary division of the isthmus should be made with a turning out of the lobes from the trachea in large goiters, as recommended by Balfour. Preserving a portion of the posterior capsule and avoiding injury to the recurrent laryngeal nerve is a satisfactory method. In exophthalmic goiter double resection largely avoids repeated operation; otherwise a small percentage of cases might require a second operation, perhaps at the end of two years, and some might require a third operation. This might be accounted for by the statement referred to previously that nature has very carefully protected the function of the thyroid gland, that some cells are unborn at birth and are constantly becoming ready for hyperplasia.

Acute Cancer of the Breast in a Girl of Fifteen.—Chauvel and Renaud report this case. The disease had appeared five months before the operation and death took place from mediastinal metastasis one month after the latter. In structure the tumor resembled closely the vegetating cystic epithelioma of the ovary.—*La Presse Médicale*

LOCAL ANESTHESIA AND SURGICAL TECHNIC.*

BY ROBERT EMMETT FARR, M.D.

MINNEAPOLIS, MINN.

THE obligation of the surgeon to his patient demands a high standard of development along a variety of lines. Diagnosis, in all that this term implies, combined with judgment regarding when to employ surgical measures and what measures to employ, must always remain the cornerstones of surgical therapy, and their establishment presents the greatest difficulties with which the surgeon has to contend. Surgical mortality and, more especially, surgical morbidity are maintained at a high level on account of wrong diagnoses and consequent misdirected surgical treatment more than from any other cause. Yet, there are other factors well worth consideration although they are perhaps of secondary importance. I refer to two of the details connected with the application of surgical therapy—local anesthesia and surgical technic.

We are constantly hearing of "standardization." When this term is used to designate an ideal at which to aim—an improvement to be hoped for—it becomes an excellent agent for advancement. When the term is used, however, as an evidence of smug satisfaction with one's achievements and marks the point at which progress has ceased it necessarily implies deterioration. It will be admitted, I think, that perfection has not yet been reached as regards either anesthesia or surgical technic. Yet we hear the remarks, "We are entirely satisfied with our method of anesthesia"; "we have no trouble with our anesthesia," etc., while, on all sides, incontrovertible evidence is presented showing that all anesthetics produce deleterious effects upon the human organism and that it is highly desirable to minimize these with all possible despatch. The same is true in relation to surgical technic. Sepsis and physical and psychic trauma associated with surgical operations have not been reduced to the lowest possible point even in our best clinics, and in too large a proportion of these the reverse is the prevailing characteristic.

In this communication I have nothing new to present, but I desire to offer a few suggestions in relation to certain refinements in surgical technic—refinements which I think the surgery of to-morrow will demand—and to offer some suggestions regarding the practical application of local anesthesia—an adjunct which the surgery of to-day is demanding and which I believe the surgery of to-morrow will insist upon.

The successful use of local anesthesia is so dependent upon the refinements of surgical technic that a joint discussion of these subjects would seem apropos, for, while a refined technic is desirable in all surgical work, it is a *sine qua non* when using local anesthesia, and a more extended use of local anesthesia will serve to influence the development of surgical technic, as it has in the past, in its approach toward the ideal.

Coincident with an improvement in surgical technic, however, there must be an even greater

*Read by invitation at the annual meeting of the Brooklyn Surgical Society, March 3, 1921.

improvement in the methods of using local anesthesia. Complicated methods should be avoided whenever possible. I cannot subscribe to the recommendation made in the monograph of Sherwood-Dunn entitled "Regional Anesthesia (Victor Pauchet's Technique)" and published in 1920, that "pelvic surgery demands the injection of twelve pairs (of nerves) on each side of the spine—six lower intercostals, three lumbar and three sacral." It is not surprising that this surgeon prefers general anesthesia "for hysteropexy, removal of ovarian cysts," etc., and that he states: "We seldom practice abdominopelvic operations under local anesthesia," or that his method of choice "for major intraabdominal operations on the liver, stomach,

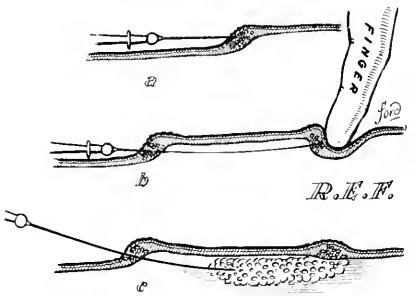

FIG. 1.—Local anesthesia. Sectional views of infiltration of the skin; *a*, first dermal wheal; *b*, painless method of making secondary dermal wheals; *c*, subdermal infiltration. (From the *Journal of the American Medical Association*, 1917.)

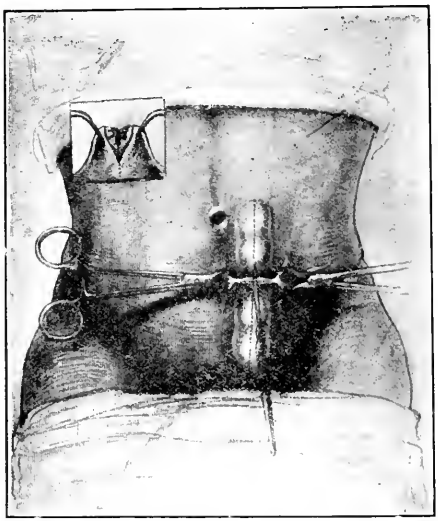

FIG. 2.—Method of elevating the abdominal wall while the incision is being made.

intestines, and pelvic organs [practically the whole domain of abdominal surgery!] is best accomplished under intraspinal or general anesthesia."

Provided these statements in any manner reflect the attitude of this great master in relation to local anesthesia for abdominal surgery we must assume that his experience in this field has not been especially gratifying. Likewise, a recent visit to the clinics in New Orleans, where observation was made of the work of Matas, Allen and Maes, showed only a prostatectomy and operation for hemorrhoids under local anesthesia in a series of thirty or forty major operations. Such evidence would seem to indicate that local anesthesia is far from a routine procedure even in the hands of those who are best prepared to apply it. It would seem essential, therefore, that more simple and efficient means be devised for using the method, and that local technic must be so simplified that the novice in its use may more easily acquire the method, and that during its administration distress to the patient must be minimized. There is, for instance, little advantage in the establishment of perfect anesthesia for a major operation provided the patient has been caused such an amount of pain during the injection that he refuses to go on with the "show" or submits to the operation under protest. And yet this is not an uncommon occurrence, and, provided we are

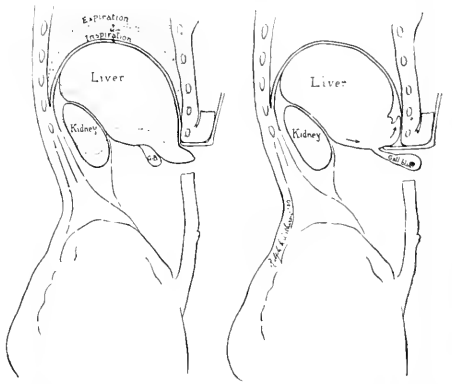

FIG. 3.—Rotation of the liver within the abdomen for exposure of the gall-bladder and ducts. (From *Minnesota Medicine*, April, 1921.)

to follow text-book teaching, this is what is to be expected in a considerable percentage of major cases.

It is my observation that repeated painful sensations of exactly the same degree cause complaints which increase in a geometric ratio—that is, the fourth needle-prick of the human skin causes four times the suffering caused by the first one. Why, then, should we follow the plan of producing numerous wheals at various points upon the skin before it is anesthetized? In 1915 I presented a method I had used for many years which renders this technic unnecessary. (Fig. 1.) Secondary wheals may be painlessly made from beneath and the subdermal injection of the line between wheals can be made in an instant, thus eliminating the time and labor-consuming infiltration of the skin. Failure to recognize these facts has retarded the success of local anesthesia, as it is usually at the beginning of the administration that psychic incompatability is at its height and the surgeon under the greatest handicap.

By the use of long needles and by making all

wheals, except the initial one, from beneath we may quickly, painlessly and effectively anesthetize a field of any proportion. Why, then, should a patient who is to be operated upon for an inguinal hernia, for instance, be compelled to suffer four needle-pricks through the sensitive skin when the desired result may be more easily and quickly accomplished by making only one? The use of such methods will continue to bring forth protests from our patients and retard to a marked degree the adoption of local anesthesia, and yet we read in the 1920 "Year Book of Surgery" an editorial note by Ochsner that *only intradermal* and *no subdermal* injections should be made!

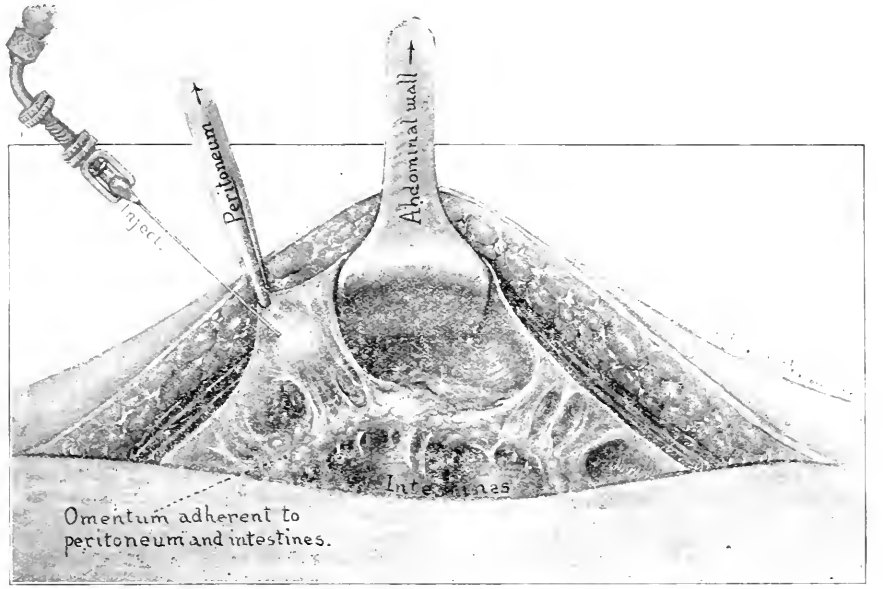

FIG. 4.—Vertical retraction showing method of handling visceroparietal adhesions under local anesthesia. (*Minnesota Medicine*, April, 1921.)

FIG. 5.—Wire retractors. (*Hospital Progress*, April, 1921.)

When surgeons realize that the administration of local anesthesia can be painlessly performed in any case in from one to five minutes so that a properly executed operation may be begun *at once* and completed without pain, and can demonstrate and teach these facts to the surgeons in embryo, our ideals will be more nearly approached.

Technic.—Equipment is one of the first essentials. Defective equipment at once interferes with the stealthy introduction of the solution. Needles should be long, fine, flexible and sharp. If syringes are used they must work perfectly and be so constructed that injections can be made at any angle desired. The difficulty experienced in using syringes led the writer to develop the Pneumatic Injector for use in this work, with the result that syringes have been entirely discarded. Speed, uninterrupted administration, with a perfect view of the field, adaptability of the cut-off, the elimination of muscle tire and consequent tremor and loss of tactile sense have converted what is usually an irksome procedure into a ridiculously simple and easy one.

The infiltration method is the one of choice except in dissections about the neck, inguinal hernia, and surgery of the skull, thorax, kidney, and the limbs—where an "infiltration-block" is added. Conduction anesthesia is confined almost exclusively to the trigeminus and the brachial plexus. Intradermal wheals are made only at the points through which the needle traverses the skin and all layers

are anesthetized routinely before any incision is made. In all cases the reflexes are abolished with a view to giving complete relaxation to the muscles, a condition so desirable in cases of fracture, dislocation and abdominal operations.

The Abdomen.—The abdomen is opened after elevating its wall by means of towel pins which grasp the skin. (Fig. 2.) Vertical retraction is continued and when the peritoneum is opened we should have a duplication of the condition which prevails in the fresh cadaver. The viscera are found collapsed, anemic, and flaccid, and are moved about the abdominal cavity as desired by tilting the operating table. Packs are used only to prevent soiling, with certain exceptions—notably, gall bladder cases where they may be necessary in order to give adequate exposure. Rotation of the liver within the abdominal cavity, instead of dislocating this organ, is practiced. (Fig. 3.) Visceroparietal adhesions are exposed by vertical retraction of the abdominal wall and then cut upon the "white line." (Fig. 4.) Splanchnic anesthesia is used in upper abdominal work after the abdomen is opened. Caudal anesthesia of four ounces of 0.7 per cent. procaine precedes the infiltration of the abdominal wall when pelvic pathology of a complicated nature is anticipated.

Retraction is made with wire spring retractors. (Fig. 5.) All tissues are grasped by and handled with instruments whenever possible, and, so far as possible, an instrument technic should be followed. The nearer the "bacteriologic" or "no-hand touch" technic is adhered to the less will be the danger of sepsis and of trauma as well, provided proper instruments are used. Knots may be tied more quickly, more cleanly, and more economically with forceps than with the hand. Long, slender, rubber-tipped instruments are much more satisfactory for reaching into the abdomen and picking up movable viscera than are the fingers. (Fig. 6.)

An effort is made to perform the required operation *where* the pathology lies rather than to try to bring the pathological tissues to the surface before releasing them. Pus tubes, for instance, may often be released from the pelvic attachments by gently exposing the retaining bands and cutting them with knife or scissors. Properly placed incisions, perfect light and daylight dissection, using the eye and knife or scissors, are recommended rather than making the dissection in the dark with the hand, no matter how well educated it may be.

Not only must we modify the technical details in relation to the method of performing operations but surgical methods as well. Universal abdominal explorations must become less common; likewise the performance at one sitting of multiple major operations. Both are incompatible with surgical ideals. Will not the more frequent use of the fractional method of administering surgical therapy, thus avoiding the profound depletion of the vital forces by the performance of a two- or even a three-stage operation, mark an advance? Would not a more frequent use of this method not only reduce the present mortality but the morbidity of surgical procedures as well? Have we not a corresponding analogy in the case of the prize fighter who may indulge in frequent boxing contests without suffering more than temporary depression, but who may be permanently incapacitated by too strenuous a beating? May not a patient be so severely traumatized through a series of surgical procedures synchronously performed that recovery will be greatly delayed or perhaps a normal condition never be regained?

I believe that the future will find surgeons more carefully analyzing the structures of the abdominal wall in relation to their relative importance and that conservation of the nerves of this region will eventually be considered more important than the maintenance of the continuity of the fibers of the rectus muscle, with a corresponding reduction in the trauma attending some laparotomies.

With more painstaking diagnoses demanded by local anesthesia incisions will be more accurately placed in relation to the underlying pathology. Within the abdomen trauma, which will not be tolerated under local anesthesia, will be eliminated to a large extent under this régime even when general anesthesia is used. Instrument dissection, the avoidance of traction, and, to some extent at least, a reduction in the amount of clamping and crushing of the viscera (which *must* be avoided when using local anesthesia) would seem desirable. Possibly anastemoses will be made more frequently without the use of clamps, which, after having played their part in the development of abdominal surgery, may follow the Murphy button. Would it not be well to eliminate, so far as possible, the forcing of the abdominal viscera into certain territories by means of gauze packs and to substitute for this method the action of the force of gravity, using the gauze only for the purpose of isolating the viscera from the operative field? Local anesthesia demands this technic, and, when perfect, allows it in many cases.

In the future the importance of comfort to the patient before, during, and after operation will be more keenly realized. He will be treated as a patient rather than as a case. Paralyses and back strain will be avoided. The safety and comfort afforded by sufficient heat and abundance of fluid will be better appreciated. Post-operative pain will be reduced by the prophylactic use of some drug like quinine to produce prolonged anesthesia and by a more gentle and refined technic, and morphin will not be withheld when its use is indicated. The abdominal organs will be more often examined visually while lying in their natural position, and the blind exploration with the gloved hand will be less commonly used, as a better interpretation of symptoms is made. In the future, surgeons will realize more acutely that pathology which can be "picked off" in some far distant corner of the abdomen by an exploration with the gloved hand can, as a rule, be anticipated by a careful history, physical examination and properly co-ordinated laboratory data. Both local anesthesia and surgical ideals make the same demands in this regard.

Time will not permit the offering of further illustrations although such examples are practically unlimited in number. However, I believe a sufficient number have been offered to emphasize the fact that improvements along the lines suggested are highly desirable.

Surgery owes a debt to those who, like Crile, have bent their energies to the development of means

by which the vital forces of the patient may be conserved. It is to be regretted that these men are occasionally characterized "dreamers" and "faddists" by some of those who are "floating on the tide," but may we not, in truth, look forward in happy anticipation to the fulfillment of these "dreams" as the surgical profession more clearly realizes the importance of the improvements advocated?

PHYSICIANS AND SURGEONS BUILDING.

ORIGIN AND SIGNIFICANCE OF MINOR VERTEBRAL DEFORMITIES.

WITH SPECIAL REFERENCE TO THE CAUSATION AND TREATMENT OF SCOLIOSIS.

BY J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF PHYSICAL THERAPEUTICS AND DIETETICS, MEDICAL DEPARTMENT, TEMPLE UNIVERSITY.

WHAT significance should be attached to minor alterations in structures adjacent to the spinal eminences, especially those occurring in children and young adults? A trained eye and touch will note, on examining the back areas of most individuals, young or old, certain anomalies of structure. Among alterations of structure are deviations in alignment of the vertebral eminences, often sudden, abrupt, some to one or other side, some projecting posteriorly and others depressed, also variations in contours of muscle masses, usually due to over- or under-tension or to spasm. Among sensory reactions are such as local resistances, or tenderness to touch. These are rarely noticed because the spine is seldom examined; but they deserve critical attention and differentiation.

The object of this inquiry is to submit evidence and offer such inferences as seem to me should be made therefrom and certain postulates for discussion.

This subject has long attracted me and I approach the solution with an open mind. My reactions to these phenomena have led me to adopt the habit of exploring the backs of most of those who come under my observation, including those variously ill or not wholly well, and those in whom no ill health is then suspected. By this means I have been led to make certain clinical inferences, here submitted. Others would be repaid by doing the same. The hints here supplied may aid in similar explorations, in choice of remedial procedures, and in applying one's knowledge of neurophysiology and pathology.

Through an accumulation of such findings much of value should come to be learned and they would supply side lights on widely diversified clinical problems. If others note the same consistency in the findings, both of gross morphology and of functional association, there should emerge uniformity of facts, also of inferences, later a consistency and a final verity of conclusions.

In due time, it is safe to aver, a body of acceptable facts would accumulate, and from them would emerge principles of procedure affording guidance to diagnosis, prognosis, and remediation.

One fact is sure: far too few physicians do explore backs, and yet fewer seem qualified to interpret findings; also the older the observer is, the less does he seem capable either of making useful observations or of differentiating his percepts. It is likewise a fact that individuals differ widely in capabilities of touch, of tactile apperception. My experience, however, with some students and with a few assistants is encouraging.

Orthopedic surgeons are known to be prompt and keen to explore the backs, but their objective seems chiefly to be the determination of gross morphogenic alterations or anomalies, and these, when found, are regarded as mainly significant of gross structural disabilities.

The nature of the enterprise it is my purpose to urge is the appraisement of the peculiar correlationships these structural anomalies bear to functional derangements, especially such as are exhibited in the sympathetic domain. May not there be both action and reaction here, leading to disorders of interaction, in which the mechanisms involved include aberrances in the reflexes, the spinal and the vasomotor mechanisms, and yet other illumination not yet clearly determinable?

The testimony available in forming interpretations of these structural and functional interactions has seemed to me extraordinarily meager. Oftentimes useful points, direct and collateral, are found as mere fragments and usually only incidental. As to methods for procedure these were presented in a paper by me, entitled: "Backache and Tenderness," International Clinics, Vol. I, series 29, 1919.

My immediate purpose is to sketch out such interrelationships as might prove to be factors in early scoliosis, in many if not most instances, along with such evidences of reflex irritation as emanate from disordered viscera, or from other areas. They are shown in altered structures lying adjacent to the vertebral discs. In the interdiscal spaces lie the cell bodies in the line of spinal relationships, which pass to the sympathetics, via the posterior primary divisions of the cord.

Summary of Argument.—We have in the field embracing disturbances of the spinal structures: the cord, the correlated sympathetic pathways, and the susceptible areas, certain groups of cells, forming a promising method of approach to the understanding of many grave clinical problems of both body and mind.

The topic is not merely that of beginning deformations of the spinal column with all their evil byeffects. There is likewise the deeply significant group of assorted origins based upon reflexopathies. These resulting disorders have not as yet been viewed with the just suspicion they deserve. They therefore should be brought within the field of scientific scrutiny. At least one group of causative factors is thus established. What may prove to be their extent or degree of incrimination remains to be tested by mass experiences. They deserve to be pursued to their finalities.

At least one group of safe, reasonable, and efficient remedial agencies are likewise demonstrated, the manual stimulation of gross reflexes. The potency of this, while still under judgment, will grow in acceptability with any one who will explore the field.

The potential or hereditary origins, the status of the chromosomes, may remain beyond present control. The biokinetic, the environmental origins, the points of departure of disordered energies, of morbid processes, are obvious enough and capable of beneficent modification. So also are the contribu-

tary, the instrumental origins, the accessory perturbations of growth and repair forces, thus brought within calculation and means of remediation.

The causative factors of any deformation are necessarily complex, long in forming, retroactionary, and almost without exception curable when dealt with early enough.

The potencies of morbid agencies vary not only in different individuals but in the same individual under fluctuating environmental exigencies. They also alter readily and confusingly under stress of emotion, of repression, apprehension, and of maladjustment. In short, the coefficient of susceptibility forms a nice problem capable of simplification by means of this mechanistic concept of the scope of reflex functioning and malfunctioning.

Among the causal factors to be reckoned with are certain obscure, elusive functions, also their retroactionabilities upon metabolism and the consequent energy leaks. The infective processes are coming to be familiar matters, but as to their natural history, tortuosities, aberrances, much remains to be learned.

For instance, Dr. Winsor has observed with surprise—and this quest is open to other observers—that the spinal columns of animals of various sorts and in remote past ages, as seen in museums, also exhibit analogous alterations in morphology. Likewise that a large proportion of these deformations resemble what is called rheumatoid arthritis. Should this hypothesis come to be accepted we may push our search for infective origins yet further.

Winsor's hypothesis that we may again come to view age degenerations as the effects of disease deserves reconsideration. Metchnikoff's postulate of intestinal infections, or hypersusceptibilities of the enteric mucosa and circulation comes in here as collaterally suggestive. Likewise we may repeat the trite aphorism that from the time we are born we begin to die. Can man ever hope to reach such a state of perfectness that the means of disease shall be destroyed? If so, then the cellular degenerations, cytopathies may merely be a slowing down, and the stream of life be conserved beyond present expectation. At the least we may hope to realize ultimately a race of men and women endowed with normal backs, and it is reasonable to infer they will also be endowed with the minimum of disorders in the autonomic and vegetative nervous domains.

A definite, constant relationship exists between certain morphogenic changes in the paravertebral tissues and many ailments. This was first pointed out in a book published in 1834 by two practitioners, brothers, named Griffin, one of whom was a surgeon in Edinburgh and one a physician in London. They reported 148 cases in which they had observed these clinical facts and shrewdly surmised the reasons.

Already a large and interesting mass of observations has been accumulated by careful clinicians and recorded in medical literature, which throws light upon the subject of reflex relationships between acute and protracted disease and the observed morphogenic and sensorigenic alterations in the tissues of the back. The attention of practitioners is not yet directed to the subject to such degree as its importance warrants.

Now for my personal opinions: Observations and study of the clinical facts alluded to above will reward those who shall take the time and trouble. They are capable of playing a most important part in both diagnosis and treatment. It is possible to produce remarkable and gratifying effects by judicious manipulations. By *injudicious* pressures, however, ill effects are not wrought, merely temporary disturbance of reflex equilibrium. This is especially noticeable in the effects produced upon blood pressure, sending it up or down, occasionally to such an extent as to seem menacing. Among certain persons, notably chronic neurasthenics, however, but small results follow. The centers in such are not only (1) relatively exhausted, but (2) the responses to stimuli are feebler, and (3) the reflex responsiveness in weak persons is feeble and soon becomes exhausted. I am able to get better results with my hands than by most mechanical devices such as "vibrators."

Furthermore, in manual diagnosis it is essential to *feel* with the hands, to apperceive by tactile sense what one is up against. In remediation, to prolong the pressures unduly, or to exert too great power, at best nullifies the desired effect, exhausts the reactionary resources of the centers.

Let me quote from a paper of my own published in the *British Journal of Children's Diseases*, January, 1905:

> Effects upon the blood supply of all parts of the body can be produced by influencing the centers in the spinal cord more directly and simply, and through them become exerted upon the sympathetic centers and ganglia, than from measures directed to the organs disturbed. *Per contra*, disturbances in the various organs, systems, and tissues, being due to circulatory changes induced reflexly from the central nervous system (the major portion of the nervous mechanism being located in the spinal cord), disturbances of the circulation in the cord are expressed by alterations in the structures and sensory functions of those parts supplied (vasomotorially) by the posterior primary divisions of the spinal nerves, as well as of the parts affected. . . .
>
> It is then to be inferred that local changes will also be manifested in the associated tissues of the back, adjacent to the vertebral column. During the continuance of diseased states, or lesser disturbances, pronounced alterations are to be observed in those tissues immediately innervated by fibers arising in the spinal segments whose integrity is disturbed by derangements in functions of organs and areas dependent (for their innervation) upon those segments. In brief, there is both a nutritive and a sensory reaction exhibited upon the erector spinæ muscles and allied structures, caused by the disturbed circulatory equilibrium in areas depending for vasomotor regulation upon certain groups of segments of the cord. There is, as has been said, a compensatory reflex relationship existing between, first, the surface muscles of the skin supplied by the posterior primary divisions of the spinal nerves; and, second, the blood vessels of the cord and deep structures, organs and remoter parts innervated by fibers whose cell bodies arise in a corresponding region of the cord. The spinal cord, viewed from the embryologic standpoint, is a cylindrical tube of nervous tissue made of the fusion of bilateral ganglia in some of the lower worms. This view of the spinal cord is essential to the proper concept of the nervous mechanisms in man and the higher animals.

Irregular practitioners of one type or another have, from time to time, attached much significance to the status of the ligaments and attitudes of the vertebræ. "Subluxation of the bones of the back," accredited as a common cause of the functional derangement, may not be accepted.

Also I have a personal letter from Prof. J. George Adami, of Montreal, to the effect that he found my explanations to him acceptable. Later see quotation from a summary of Dr. Henry Winsor's researches.

To quote further from my earlier paper:

Relaxations of the lateral, and posterior spinal, ligaments are due chiefly to nutritive faults. There is produced often the appearance of dislocation, but most of these morphogenic phenomena disappear upon restoration of tonus in the shrunken tissues, chiefly through mechanical stimulation. Attempts to "replace" these so-called "dislocated bones" and to relieve pressure on nerves—the creed of the osteopath—sometimes results in benefit, not so much by accomplishing the object aimed at, as through the effects wrought upon the centers of vasotonus and the lymph activities by mechanical or other reflex stimulation. Where, as sometimes happens, undue force is used to "pull or push" these tissues in place, harm is often wrought of which little is said, or to which other causes are assigned. It is an interesting but significant fact that any agent which causes vasoconstriction in the tissues of the back, contiguous to the spinal column, will produce, conversely, dilatation of the vessels in the cord and of the organs and parts beyond the line of innervation.

Any agent which produces dilatation of the vessels supplying the tissues of the back, will, by compensatory action, induce constriction in the blood vessels of the cord and parts beyond. The clinical significance of this is at once made plain, and its value, not only as a factor in diagnosis, in treatment, but in expediting nutritive changes, is readily demonstrated.

On inspecting the back of one who is, and has always been, perfectly sound, there will be seen (if certain attitudes are assumed to bring them into prominence) the spines of the vertebræ in normal alignment, distance apart, and degree of posterior projection. If there has been a history of long continued or recurrent disturbances of the internal organs, these disease effects are frequently revealed by alterations in the tonus of the blood vessels, and of those muscles, and other tissues innervated by, or lying adjacent to, the governing segments of the cord from which the organs at fault are reflexly controlled through their vasomotor connections. The change of form exhibited is an atrophy of some, infiltration and thickening of others, and if long continued, asymmetries of the vertebræ, the spines apparently pointing in different directions. If the lesions have become chronic, the spines are often found separated owing to relaxation of the posterior ligaments, until between two or more there appear marked depressions, or several show depression below the normal line of projection. This disarrangement of the vertebræ in young children and when recently formed in adults, is more apparent than real, the asymmetries here being mainly due to loss of tone and relaxation in the supporting ligaments, and this often disappears under appropriate treatment.

A recent series of careful dissections was made of over fifty bodies by Dr. Henry Winsor, prosector to the Anatomical Rooms in the University of Pennsylvania, with the object of learning what anatomic evidences exist of alterations in structures of the spinal column, and associated effects of disease in areas innervated from the same cord levels or sympathetic segments. These findings will be published in full. I quote from a personal letter:

The point I have constantly aimed to determine is that curvatures of the spine and other vertebral distortions, nearly always are found on the line of the same sympathetic segment as the viscera which are diseased. While the vertebral distortions appear to occur first, and the visceral pathology appears to be secondary, the reverse may also be true. The visceral reflexopathies appear to make the vertebral distortion greater, while the vertebral malformations exaggerate the visceral disturbances, the rami communicantes containing both gray and white fibers. I have been doing many more post-mortems since giving special attention to the veretbræ involved in curves. Most of the vertebræ in a curve exhibit deformities, in discs, in centra, in pedicles, in lamina, in articular processes and in spinous processes. The variations found by Wallace were necessary to the Darwinian theory. The bilateral asymmetry of the vertebræ explains the persistence of curves of the skeletons I examined in museums. The discs and centra are deformed by pressure and counter-pressure, above, below or laterally. The pedicles, laminæ, and processes are the result of muscle pull normally. When asymmetrical, the muscle pull has been unequal bilaterally, the result of unilateral muscle spasm from irritated nerve reflexes. Spinal curvatures cause distortion of the vertebræ, and distorted vertebræ cause spinal curvatures. One exaggerates the other; as you say, the element of statics enters into the problem. If subluxations exist they would cause and result from distorted vertebræ. The distortions are irreducible. Manipulation, when it is effective, improves the patient's condition by restoring motion and relieving the neighborhood of the joint from adhesions, thus releasing the blood and lymph supply and nerves of the joint from the effects of a peculiar callous which tends to collect around all distorted joints. The steps or stages of a continuous process appear to be as follows: nature attempts to fix, to immobilize, an irritated or distorted joint. The muscles then become tendons, tendons become ligaments, ligaments become cartilaginous, cartilage becomes bone, and then fixation results. Only by boiling the bones can they be separated, and then often with difficulty, into the two bones which were apparently ossified together. As the muscles pulled the bones out normally into processes, so do the muscles and ligaments pull the processes still more abnormally when the muscle pull is wrongly directed or is stronger on one side or on the other. The end stage of this condition is rheumatoid arthritis. I have demonstrated all the intermediate stages from distorted vertebræ in curvatures of the spine, to advanced rheumatoid arthritis with ankylosis. Rheumatoid arthritis affects the neighborhood of the intervertebral discs. The pull of the anterior common ligament causes exostoses to develop. Rheumatoid arthritis confines itself, usually, to vertebræ that are deformed, and are parts of an abnormal curve. The anterior common ligament is pulled by the psoas and diaphragm, the ligaments around the heads of ribs, the stellate ligaments receive fibrous expansions of the anterior common ligament. Hyperextension stretches this ligament, flexion of the spine relaxes it. Old age is so commonly associated with rheumatoid arthritis, at necropsy, that we might say that old age is a result of rheumatoid athritis, not a cause of it. Clinically, patients may appear to die of old age, the necropsy will show they practically all die of disease. Old age is probably a disease and might be called rheumatoid arthritis. Boiling is needed to dissolve the callus around these deformed joints. Pleurisy with adhesions compresses and pulls on the sympathetics; pleurisy causes pneumonia rather than that it results from pneumonia, by irritation of the sympathetic nerves going to the bronchial arteries from the upper thoracic nerves by way of the posterior pulmonary plexuses. Cardiac disease can occur in the same way from pleural adhesions affecting the intercostal nerves and setting up sympathetic reflexes, or by affecting the cardiac nerves and the cardiac filaments to the cardiac plexuses. Emphysema—the breathlessness, or dyspnea of emphysema—is probably not due to overdistention of the air-vesicles as we have been taught. No matter how overdistended they might be, great pressure could collapse them. The loss of expansion is not due to the fact that the lung is so expanded that it cannot be expanded more, nor is it the result of fibrous pneumonitis, although these are minor factors. The real cause seems to be that the ribs are rigid, the chest cannot then expand or contract because the joints of the ribs are immobilized, not only by reflex-irritation (tonic protective spasm) but also by rheumatoid arthritis developed as a result of vertebral and of rib distortions. I have frequently seen rheumatoid arthritis of both ends of many ribs in several subjects at the sternal as well as the vertebral articulations. The fixation of the ribs causes the entire work of respiration to fall on the diaphragm. The accessory muscles of respiration pull violently, but are unable to move the ribs, and then the chest cannot expand or contract. Springing the ribs, by

compressions, mobilizes them, improves their vigor.

One must observe vertebræ carefully. Nature has a way of compensating and obscuring her imperfections. The first impression that one obtains on looking at some of these vertebræ, is that one's eyesight is wrong, one feels as though one had astigmatism uncorrected. By reversing the vertebræ, by turning them around, the defect is seen to be not in the eye, but in the object. All the various parts, or rather *any* of the parts of the vertebræ, may be affected by distortion in many different directions. The nucleus pulposus of the intervertebral discs is in all probability only relatively displaced, the disc having changed its shape, being thicker on one side than the other, or thicker in front or behind. This change in shape may be normal in some parts of the spine, but makes the nucleus pulposus appear to be displaced. The vertebræ appear to be displaced by the changes in the shapes of the vertebræ, the ones above, or below, or all three may be out of line antero-posteriorly or laterally because of these distortions.

Sympathetic irritation may be a cause of high blood pressure and arteriosclerosis. The fibrous and callous formations adjacent to these distortions, are probably the direct cause of pressure on the nerves as they leave the foramina, or a toxic or bacterial invasion of the sheaths of the nerves may occur. The blood vessels going to the cord may be involved, thus influencing the vein and arteries of the cord or nerves. This change in the blood supply acts as a possible cause of disease in the cord or nerves. Both the sympathetic and the somatic blood or lymph supply of the neighborhood could be affected. It is only fair to assume that the sympathetic, which has so long been considered a prime factor in healthy physiology, should come to be an equally important factor in diseased physiology and this fact might be utilized to restore health.

We may recall in this connection the fact that orthopedic surgeons tell us that in cases of minor scoliosis the alterations in morphogenesis of the spine can be made frequently to disappear or to become negligible. The reason for this subsidence of deformations or lesions is generally accredited to systematized and suitable, or even spontaneous, exercises whereby the opposing muscles regain tone, nutritive balance is restored, and reflexopathies disappear. Since the course of treatment usually includes a general, and often special, course of hygienic, dietetic, and therapeutic measures, it is reasonable to infer that a good deal more has been achieved than by mere muscular, tendinous or ligamentous reestablishment.

My impression is that a much deeper import can be claimed for the steps of progress. I wrote a paper entitled: "Hypothesis as to the Causation of Scoliosis" (*Monthly Cyclopædia and Medical Bulletin*, September, 1904), copies of which were sent to a number of orthopedic surgeons, with a letter of request for cooperation in observance."*

Assuming that my explanation shall at least in part come to be established, it will be seen that in it we have both "bane and antidote," a revelation of origins and promises for better remediation than by mere exercises alone.

My experience is now sufficiently ample to justify the conviction that there is opened up a promising resource in manipulative measures designated to quiet down the local irritation in the erector spinæ muscles, to release the tonic protective spasms, to release excessive intraarticular pressures, to expedite nutrition through enhancing the vasomotor ebb and flow, to drain away vitiated blood and lymph, to reestablish poise in the spinal visceromotor as well as the sympathetic vasomotor reflexes and to encourage or abet the fuller efficiency of the motor reeducation (kinesitherapy).

The causative factors of scoliosis are proverbially obscure, complex, and elusive. So far as can be learned there still prevails much disagreement and some loose conjecture. We are still in grave need of light on the subject of growth forces and their variants. We recognize certain periodicities of stress, of advance, of retardation, of lowering of the defence reactions, and perturbation of the balancings of energies. These lowerings of the factors of safety induce yieldings to pressure exerted from stress of environmental disadvantages and also from within, inducing imbalances in the energies of the ductless glands.

How and where does the trouble begin? Up to date we know too little of conditions which induce energy leaks or impairment, but we do know that the governor to the human engine lies in that group of energy regulators, the endocrines and through their agency much can now be done with confidence.

Furthermore, we are coming to know with increasing certitude that much, perhaps most, can be achieved through orthokinetic readjustment, the repoising or reestablishment of the reflexes, the enhancement of general and local nutrition through directing vasomotion.

A crude empirical grouping of the continuous process of diagnosis and treatment will be found in the following typical case.

A girl was under my professional care from early childhood to marriage. At the age of fifteen I made a deliberate examination and found two spinal curvatures, one in the upper thoracic region and the other in the lower thoracic and upper lumbar; the deformation was less of compensatory curves than malalignments, with slight over-prominences of the fifth to the ninth, followed by an abrupt drop, depression, or anteriority below, also the same kind of irregularities in the tenth, eleventh, twelfth thoracic, and first and second lumbar.

These alterations were just such as would indicate to me long irritation of organs whose innervation arose in the corresponding interdiscal spaces. Now it so happened that I had attended this girl in all her childish ailments. One was a long protracted bronchopneumonia and the other was a severe disorder of her colon, and there was practically nothing else.

When she was about fifteen, I took the girl to an orthopedic surgeon, who pronounced the state a double curvature of irregular type, and he said she might possibly be cured in two or three years, but it was doubtful if entirely. In six months I submitted her to him again, after treating her by manipulations, and he could find nothing amiss.

*The responses varied widely, though in the main interest was alert. A few seemed impressed with the significance of the observations, notably John Dane, R. W. Lovett, E. H. Bradford, J. Chalmers DaCosta, Roswell Park, and A. R. Shands. Those most encouring were Nicholas Senn who said: "Your viewpoint represents the scientific side of the question and meets my approval"; and Roswell Park: ". . . I believe your hypothesis and suggestions are of great value . . . feel greatly obliged to you for calling my attention to it." Unfortunately I did not call upon these various gentlemen to search their material and make further observations.

In a large number of records in dispensaries, examined with a view of determining significant clinical incidents, I found very few were mentioned. The questions are asked casually and with no particularity in order to illustrate the difficulties in obtaining reliable facts as to antecedent ailments capable of acting as causes for the spinal irritation, let me cite a case which came to me while writing.

Hannah Siegel, aged fifteen, suffering from chorea, also a marked general scoliosis. Stout, ruddy, five feet four inches, weight 170 pounds, breast fed, always healthy, good nutrition and sleep. The mother declared positively "she had had *no illnesses*."

Upon close cross questioning and scrutiny, a history was elicited of: (1) headaches, left side, since earliest memory. (2) "Spots in the eyes," "moving over toward the left," long under the care of a prominent ophthalmologist, Dr. Burton Chance. His opinion is that the condition is an interesting one of congenital degeneration of the retina, without the pigmentation which usually accompanies degeneration. (3) Scoliosis, moderate, noted several years ago, involving the whole spine. (4) Had a bad tooth, "jaw swelled up," three or four years ago, removed. (5) Is always short of breath after running, and often has a pain in the side. Heart sounds fair but dubious. (6) Has had fluctuating pains since earliest memory, in different parts of the body, sometimes severe and laming in the leg, or foot, or knees, or back. (7) I find diseased tonsils which now demand removal and seem a source of sepsis. (8) Also she now comes to me for a chorea, so severe as to affect the voice.

APPENDIX

In commenting on this manuscript, Dr. John Dane of Boston writes as follows:

"I have read and reread your paper carefully, and am delighted with it and agree with a surprising amount. It seems to me most timely. Get it into print very soon. Its lessons are bitterly needed. Why, only a few weeks ago a young medico, trained at one of our most progressive hospitals, said that in all the examinations that he had seen made, not once had the patient been turned over onto his face to examine the back and spine. You have got to begin at the very bottom to teach what you and I *know* to be true, and so very, very important. In fact I could wish that the quotation that you make from your own work published in 1905 could be printed boldly at the beginning of every treatise on medicine. It is the key to much that we know, and still more that we do not yet know.

"I attach the greatest significance to the status of the ligaments and the attitudes (or rather positions) of the vertebræ. There is not only an 'appearance' of subluxation as you say (of course there is no question of 'dislocation') there is always a change of position, and in nearly every case one that can be demonstrated easily by palpation. Lastly, when by some form of manipulation this displaced vertebra, (or vertebræ) is made to retract the path by which it has become displaced, the symptoms vanish and you find that the position of the vertebra has become normal. Why hesitate to say the vertebra has been replaced and that that is the cause of the beneficial result? I am not saying that there is, or has been, any 'pressure of bones upon nerves' or any of the stock explantions of osteopaths. My working theory has been always that reflex-sympathetic action is the only explanation of the phenomena. My idea is that some such chain of sequence of cause and effects arises as this: By some sudden movement, or one made when the opposing muscles are off their guard, one or more joints are carried a little beyond their normal limit of motion, and become jammed there. This stretches or perhaps ruptures some fibers of the protecting ligaments, and a mild grade of synovitis of the joint is set up. This at once starts the reflex mechanism through the sympathetic; the muscles about the region are thrown into spasm, which prevents further motion from unlocking the joint in most cases. The patient frequently has a sensation that something has slipped, and not infrequently hears a snap when the joint is displaced. Once the sympathetic reflex gets to work I think we are agreed upon the general way in which it acts, and causes trouble wherever the anterior branch of that particular nerve is distributed. I also believe that the reflex sometimes works in the opposite direction, *i. e.*, if the terminals of the anterior branch are irritated, it is reflected to the posterior branch which causes contraction of the muscles of that sympathetic segment. Given this contraction any motion of the back as it travels along will come upon the resistant section, where instead of being taken up by elastic structures it pulls upon relatively non-yielding muscles that are in spasm, and this soon subluxates more vertebræ, and starts off a secondary set of mischief-making reflexes.

"In your quotation from Winsor, while I heartily agree with much he says, if he uses 'adhesions' in the sense that I do, you will see that in such cases as I am considering it is too early to speak of any having formed. His series of stages in the production of arthritis deformans is admirable if you will let me make one important addition. I do not believe that it occurs unless there is some irritating substance circulating in the blood; as this is most often a result of faulty intestinal metabolism, the lesion in the back if it is so located as to interfere with the innervation of the splanchnics will supply abundant cause.* I think that wherever the terminals of a nerve are situated, whose origin is in an irritated section of the cord, there you find an area of lowered vitality which not only causes pain and interferes decidedly with the performance of function, but there bacteria easily overcome the resistance of the tissues and start to grow."

1504 PINE STREET.

ENCEPHALITIS COMPLETA.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS.

BY J. VICTOR HABERMAN, A.B., M.D., M.S.D. (Berlin).

NEW YORK.

(*Concluded from page* 140.)

PONDERING some of the titles of recent publications (*i.e.* Influenza Encephalitis, Postinfluenzal Encephalitis, etc.), the question arises, is the influenzal encephalitis referred to a grippe encephalitis, or is it the epidemic-encephalitis of recent ill fame, and for which grippe has very widely been held responsible, or are these indeed one and the same distemper? The matter has scarcely come up for differentiation in individual cases in our own literature and but a few times abroad (*cf.* 22). This will be gone into more carefully in our study of primary encephalitis; here, however, a brief series of similarities and differentiæ may advantageously be given:†

The etiological virus or organism of both (as also that of Heine-Medin disease) remains unknown.

This virus in influenza (also in H.-M. disease) has been "grown," carried over to animals and the strain continued by passing. It has been four times reported as accomplished in the case of ep.-encephalitis,‡ and many times reported as not being accomplished—hence, still needing verification.

All three diseases occur sporadically, in groups, epidemically and pandemically. All three also occur in mild form as "abortive" cases.

All three cause a diffuse and widespread infection in the human body.

*This topic is elaborated in D. Winsor's completed paper.

†One may also instructively bring Heine-Medin disease (poliomyelitis) into the differential discussion.

‡Strauss and Lowe, Levidetti, Thalhimer, McIntosh.

All three cause a "hemorrhagic" condition, the microscopic pathological changes being not very dissimilar, and, often enough, almost the same.*

In influenza and epidemic-encephalitis the hemorrhagic tendency is decidedly "punctate." There is also a tendency toward hemorrhage into various organs of the body in both, far more pronounced in the first.

All three diseases are strongly neurotrope.

Heine-Medin disease affects children especially (preponderantly): sporadic cases possibly only occur in children. The other two infections affect both children and adults, but adults especially.

Sporadically all three diseases may occur at any time; but epidemically, grippe and epidemic-encephalitis are usually (not always) winter or early winter diseases, while Heine-Medin disease is usually (not quite always) a summer disease.

Disposition to influenza is very great, almost universal; disposition to epidemic-encephalitis is very slight in proportion, minute. The disposition to poliomyelitis is greater than to epidemic-encephalitis, yet much smaller than to influenza. From the point of view of direct contagiousness, this also is almost universal in influenza, apparently very slight in both epidemic encephalitis and poliomyelitis. As to immunity, second attacks are common in grippe, do not seem to occur in Heine-Medin disease or epidemic encephalitis.

In influenzal encephalitis there is *always* a history of preceding Grippe infection, or it supervenes on a catarrhal (mostly pulmonic) process. It is distinctly secondary to a systemic infection.†

In epidemic-encephalitis there is very frequently a history of grippe having recently occurred in the patient, or having prevailed in his neighborhood. *But* there are many cases which show no such influenza association whatsoever.‡ Decided catarrhal symptoms are, on the whole, most unusually noticed (l.c. Strümpell). It is distinctly primary.

Influenza shows up one year as especially symptomatically gastric, again, pulmonic, again, neuropathic. It has never been choreic, myoclonic, "Parkinsonian" (*i.e.* "extrapyramidal"). (Nor do we remember ever finding influenza the cause of sporadic chorea, or myoclonus.)

Epidemic-encephalitis has not shown similar symptomatic forms, it has never been a distinctly gastric or pulmonic disease; it has shown up at times in large groups, or in special localities (almost epidemically), in variations from the "lethargic" type, being here outspokenly choreic, or "Parkinsonian," etc.

Finally, and here are the really important facts:

These three, in many respects, similar diseases, all producing much the same pathological lesion, have each *a different locus-electivity* for the cerebrospinal nervous system.

Influenzal encephalitis is almost wholly convexity (cortico)-elective. Where many such cases were reported, as in the 1890 epidemic, the encephalitis was cortical, motor, chiefly one-sided, *with cortico-pyramidal symptoms* (real spasticities, paralyses, abnormal reflexes, etc.).

Epidemic-encephalitis is not at all cortical in this way,* but is basal (ganglia)—midbrain—and medulla-ponto-elective, *with frequent extra-pyramidal tract symptoms*, and rarely ever outspoken corto-pyramidal signs.†

In influenza, involvement of the cranial nerves but very seldom occurs (*cf.* No. 20; No. 2, p. 902; No. 31, p. 248), the facial when affected being unilateral and part of the hemiplegia obtaining. Nor does a diplopia, etc., ever initiate the attack. In epidemic-encephalitis, involvement of the cranial nerves is of commonest occurrence, affection of the occulomotor being almost pathognomonic (*cf.* No. 7). This last often initiating the disease. Involvement of the optic nerve is rare in both.

Several other symptoms are come upon very frequently indeed in epidemic-encephalitis, which occur only most rarely (or not at all) in influenza and H.-M. disease, namely, involvement of the sphincter iridia leading to sluggish or absent light reflex (this is very important [Nonne]), hiccough, which at times may be the only symptom of the disease, and twitching of the abdominal wall.

Both influenzal encephalitis and epidemic-encephalitis are non-spinoelective (similar to the majority of the toxic-infectious diseases‡ and so in great contrast to Heine-Medin disease.

Heine-Medin disease is only minutely § cortico-elective; it is (to my knowledge) never basal-ganglia-elective; it is considerably ponto-elective (the facial case being probably far more prevalent than our literature intimates) and is preponderantly spino-elective.

When paralyses rapidly appear, are maximal from the start and soon regress, Heine-Medin disease must be thought of. Residuals of paralyses also speak for Heine-Medin disease.

Symmetrical cranial nerve paralyses speak *against* Heine-Medin disease, in which they *very* rarely ever occur.

That this differentiation can be carried out in the majority of adult cases is very probable. Whether it can be done in the case of young children I cannot say, the reports of such cases (careful reports) being as yet meager. No doubt, however, the same applies.

That there are similarities, or relationships, of some kind between the etiological organisms of these three diseases is highly probable. Can one

*Influenza may also give a serous and a purulent meningitis. Neither of these conditions has been reported in epidemic encephalitis. In Heine-Medin disease there is never purulent meningitis, though there is very frequently meningeal irritation, giving a lymphocytosis and a general picture of the meningitis serosa type. Meningitis serosa may occur *per se* as an expression of H.-M. disease l. c. 29).

†There is a small group of *primary* cases which are to be excepted. They, however, belong chiefly to the *encephalitis inferior* cases and need differentiation from Heine-Medin disease, rarely, if ever, from epidemic encephalitis.

‡Nonne, in a very able study of the subject,[25] comments upon this fact. Economo in a recent report also states that in the majority of epidemic-encephalitis cases there is no history of grippe (*Wien. kl. Woch.* xxxiii, 16-17, 1920). Strümpell points out that the high-water mark of the encephalitis-spread in Vienna was reached in 1920 at a time when influenza was practically extinguished. Reich cites a case of a patient having had epidemic encephalitis, who later came down with sever influenze on being exposed to this disease (*Schw. med. Woch.*).

*That there is a cortical involvement is evident through the psychotic symptoms so often present. But it is not a motor-area involvement giving cortico-pyramidal symptoms (cf. above.)

†Here probably pressure symptoms.

‡Only a handful of cases are on record in which pictures similar to poliomyelitis were produced by the infectious diseases, and these were usually of the Landry's type. A recent communication of Stertz (*Zeit. f. d. ges. Neurol. w. Psychiatrie*, xxi, 5-6, p. 363) mentions an epidemic-encephalitis case in which there was an involvement and damage of the anterior ganglion cells of the spine. But nowhere did this damage lead to a total disappearance of cells as would have been the case in poliomyelitis. Another autopsied case has recently been reported. (*cf.* subsequent paper.)

§Much more minutely than is brought out by textbooks, all of which speak (following Wickman) of the "encephalitic form" of Heine-Medin disease, and comment no further (see, for instance, the Report of the Health Department of the City of N. Y.). Wickman himself, however, saw not a single case in the great Swedish epidemic, and but once heard of such a case. And in the whole literature he could scarcely get a dozen cases together (if they number that many), which, from clinical findings, must have been "cerebral" in type.

or other change its *trope*, or become *aberrantly*- or *multi-trope?* In the case of influenza and epidemic-encephalitis, a recent report of Schlesinger's[28] is highly suggestive in this connection. A young man with grippal pneumonia is put into a ward. The day after, his four bed-neighbors contract high temperature. Three are comatose. One goes to pieces with lethargic encephalitis (also has a typical grippe pneumonia), two recover, the fourth also goes through grippe pneumonia and four weeks after shows the picture of "choreiform encephalitis." Interesting here are also the serological studies and findings of Bieling and Weichbrodt,[27] who conclude that influenza-agglutinin occurs in the blood of grippe cases (and increases in the course of the disease); likewise in the blood of epidemic-encephalitis cases agglutinin against influenza bacilli is formed, and complement-binding substance, even if in but minute quantities, are produced. Hence, one must deduce that in the latter disease the influenza bacillus play some important rôle, and that both diseases are *serologically* related. (Symbiosis and also previous sensitization of the body by grippe must likewise be considered.)

Whatever the relationship, ultimately determined, between these two forms of encephalitis, the data just presented are sufficient to differentiate two types (whether of the same or various etiological factors) which may interpretatively be captioned the encephalitis *of Leichtenstern* and that *of Economo*.

In regard to influenza and Heine-Medin disease, the possibility of such a connection came up in a case of Oppenheim's I had occasion to study and later publish (among a group of cases from Oppenheim's clinic[28]). We decided against the inference in that particular case. Still earlier Wickman[29] in his studies brought up the point and also came to negative conclusions. Others since then, however, have mentioned the similarity of the pathological picture and again have surmised the possibility of some relationship. Brorström[30] of Sweden, on the other hand (and Öhlin, of Sweden, adds an affirming report), comes out with the strong conviction that poliomyelitis *is* influenza. Brorström's book is scarcely convincing, and in many parts displays loose writing and not very sharp observational acumen. Nevertheless, there are cases cited here which give us something to think about and show up evidence in the light of his thesis not entirely negligible.

Pertussis Encephalitis.—A special word must be said of *pertussis* or *post-pertussis encephalitis*. In pertussis "apoplexies," as well as grave cerebral comatose states, are seen with high temperature, convulsions, pareses and paralyses of cranial nerves, unequal pupils, spasm or pareses in the extremities, et cetera. The picture at once connotes hemorrhage or meningitis. The liklihood of hemorrhage occurring under the intense strain induced by paroxysms of coughing, especially when one considers the possibility of the blood vessels themselves being invalidated through the toxin or infectious agent of the disease (Neurath), is very great. Yet, on the other hand, one remembers that cerebral hemorrhages rarely occur in epilepsy, in spite of the great violence of attacks. Again, Wilbrand and Saenger[31] report that, though it is common for conjunctival hemorrhage to be seen in both pertussis and epilepsy, but very rarely indeed, if the vessels are not diseased, is there bleeding into the retina (*l.c.* p. 189).* Thus one comes to the conclusion that, though cerebral hemorrhage does, even if but rarely or infrequently, occur (Heubner, Holt), most of these serious pictures are rather due to hemorrhagic *encephalitis* (Henoch, Fürbringer, Finkelstein, Neurath, etc.)—and clear up.

Holt suggests that many of these cases are caused by meningeal hemorrhages producing mono- or hemiplegia, aphasia, facial palsies, disturbance of sight or sensation, all of which may disappear at the end of a week—some cases, however, proving fatal. Elsewhere Holt (*l.c.* p. 960) mentions that transient disturbance of sight occurs, even blindness of a few days to weeks, which later clears up, the milder depending probably upon circulatory changes during paroxysms, the severer upon meningeal hemorrhage. Pertinent to this matter, however, Finkelstein (*l.c.*, Vol. i, p 192) cites an interesting case with necropsy (and further literature), in which quite a different condition obtained. He mentions the comatose-meningitic picture of certain pertussis patients with severe convulsions, in which after a brief hyperpyrexic course, death supervenes and one expects to find a hemorrhage or encephalitis—and finds nothing but a serous saturation, fluid in the ventricles and flattening of the giri, the microscopic examination evidencing only the inflammatory infiltration of a *meningitis serosa*.

E. F., one year old. Following a severe paroxysm on 26.1, severe convulsions. High temperature, coughing, vomiting, bronchitis, 8.2, irritability, somnolence, transient strabismus, jerking in the extremities, together with increased bronchitis. On the tenth the temperature rises to 40.5°-41° as convulsions set in, repeated many times, also in following days. Between these attacks sopor of changing intensity. Right-sided abducens paresis, strabismus, unequal pupils, stiffness of the neck, automatic movements, spasms and paresis of extremities, considerably severer on the left side. 5.3, severe convulsion with exitus. Necropsy: mild ependymitis of the lateral and fourth ventricles and slight hydrocephalus internus. Bronchitis. Brain itself negative.

Acute Hemorrhagic Encephalitis Superior.—We must finally touch upon a form of hemorrhagic encephalitis, involving the nuclear region of the 3rd nerve instead of the cortex as in the majority of the cases thus far noted, a form first described by Wernicke and since then accepted as a definite clinical entity. It is an acute inflammatory nuclear disease—to follow Wernicke's own description closely (No. 8, p. 240)—in the region of the nuclei of the nerves of the eye muscles, ending fatally within 10 to 14 days. An associated eye-muscles paralysis comes on suddenly and rapidly *progressing to an almost total (external) ophthalmoplegia*, the sphincter iridis and levator palpebrum remaining intact. General brain symptoms also occur, namely, somnolence, either from the start, or first becoming ap-

Cf, the "X" or Mysterious Disease (Encephalomyelitis) in New South Wales several years ago. l. c. Cleland and Campbell, *Lancet*, May 24, 1919, also *M. J. of A.*, March 16, 1918.)

*Nevertheless Wilbrand and Saenger do note a case (of Landesberg) of hemorrhage during pertussis in a boy of seven. (In a later volume the authors mention this case as due to emboli of the central retinal arteries [vol. xxxii, p. 867]). See also Reference No. 34, p. 211.

parent after a period of agitation, with disorientation, confusion, or delirium, very similar to delirium tremens, furthermore headache, vertigo, vomiting and exhaustion (or great fatigue). *The temperature is for the most part normal,* the pulse and breathing rapid. *Optic neuritis or hemorrhagic papillitis were always present.*

Later studies, especially those of Boedeker (Charité Annalen, xviii) practically substantiated the above, with the exception that we now find that "associated paralyses" need not occur and that the sphincter iridis and levator may be involved (*l.c.* No. 31, p. 264). Occasionally (rarely) the facial in its lower branch has been found involved. Speech is hesitating, tremulous, unclear. Some contraction of the neck has been noticed. The lower extermities are usually affected, showing unsteadiness, stiffness and ataxia (reminding of the gait in alcoholics).

The disease occurs almost wholly on the basis of *severe* alcoholism. One of Wernicke's cases, however, was due to sulphuric acid poisoning. A case of Oppenheim's seemed to point to lysol poisoning. Other toxins (influenza, possibly?) may in all probability give the disease. Most cases are rapidly fatal, some have recovered (Oppenheim).

It is interesting to know that the agitation, delirium and disorientation also occurred in the non-alcoholic cases, so that these symptoms must be attributed to the encephalitis superior and not to the chronic alcoholism. The diagnosis is easy if alcoholism is known or suspected, and visceral lesions point to chronic indulgence. Still the disease might be confused with delirium tremens. One must think of it also where other poisons have been taken and one finds eye-muscle paralyses, changes in the optic discs, a possible facial involvement, and spastic-atactic-like disturbance in the lower extremities.

With the exception that here *the levator and sphincter iridis are more often uninvolved,* there is an unmistakable resemblance to epidemic encephalitis. It may also be interesting in this connection to cite a recently reported case of veronal poisoning[2] (and several somewhat similar cases have been noted in the literature) which shows that poisoning with this drug may likewise produce a diagnostically embarrassing situation.

Patient, thirty-three years old, brought to hospital somnolent. It was learned from friends that patient when despondent would take large doses of veronal. A large dose had rendered her lethargic for ten days in January, 1919. Again in April. In November she took a dozen 5 grain tablets, became somnolent, and was in hospital four days. In December took six 5 gr. tablets.

Examination showed profound sleep from which patient could be aroused with difficulty. When awakened, gave intelligent and coherent answers—and fell asleep again. There was no involvement (paralyses) of extremities. The right eye exhibited slight ptosis and weakness of external rectus. There was diplopia (also present in previous attacks). P. 84, t. 98. On next day, t. 100, p. 88, r. 20. During following days, however, t.p.r. normal. Lethargy slowly subsided. In March the patient again was brought in after taking ten 5 gr. tablets and turning on the gas. This time, however, there were no eye symptoms.

Another form of acute hemorrhagic encephalitis *superior,* and which must be differentiated from the above (Wernicke type) is that of Heine-Medin disease (poliomyelitis). This will be described under Heine-Medin disease in a later chapter, likewise the *inferior* form which is primary.

Pathology.—Though individual cases have brought up variances that have led to controversy, the larger number of infectious-toxic cases show a pathological picture that may be summarized as follows: If autopsied directly after the illness, the abnormal changes consist of hemorrhagic patches, sometimes very minute, sometimes as large as walnuts, occasionally single and circumscribed, more often multiple, and grouped or diffusely scattered over large areas of the brain. At times adjoining areas of the hemispheres are symmetrically involved. At times, too, it is impossible to tell whether inflammation or hemorrhage has taken place, or indeed both. Gray and white matter are affected, with *tendency,* as already mentioned, to compromise but one hemisphere and the motor elements of such (hence, subsequent spastic hemiplegia).* Where the cortex is affected, the soft meninges above are also involved, the pia adhering. The central gray, and the walls of the 3rd and 4th ventricles and of the acqueduct of Sylvius, are often involved.

Microscopically one notes an overflowing of the arterioles, with extravasation of blood white cells and fibrinous exudate, with here and there breaking of vessels.† Round cells gather in the walls of the vessels and beyond, especially lymphocytes and plasma cells; polynuclears are unusual. The neuroglea cells may multiply. The nerve elements may evidence secondary irritation and destruction. In occasional cases this, however, seems to be primary —a kind of necrobiosis, as Oppenheim assumes, in which the nerve elements go to pieces while the round cells over-proliferate. (For *pathology* see No. 1, p. 25 *et seq.,* Ziehen in No. 15, and the recent study of C. A. Homén, Arb. Path. Institute, Helsingfors, 2 H. 1 and 2.)

The spinal fluid shows nothing that is characteristically abnormal, hence lumbar puncture avails little save in aiding the diagnosis "by exclusion." This chapter will be given in full under Differential Diagnosis.

The active process once come to an end, absorption of the inflammatory products and extravasated blood takes place. Thus great improvement may rapidly set in, at times even severe cases entirely clear up. Often, however, scar-tissue forms here and there (patches of sclerosis). When the condition has been rather diffuse, a process may develop which subsequently leads to the picture of *diffuse sclerosis* (the exact facts of which are still, however, unclear). Where the inflammation has been in the cortex, the areas, after absorption of the exudate, or especially if there has been destruction or softening of tissue, is found depressed, or "scooped out," or hardened through connective tissue and glia infiltration. The destroyed area again may have been so large that a hole is left or hole-like defects—*i.e.* porencephaly. Or, finally, fluid may gather between the depressed area and overlying meninges and so form cysts. *Thus the end results as they are come upon years later* are sclerotic depressed or hardened areas, porpencephaly and

*Of secondary encephalitis as the cause of most cases of "cerebral spastic paralyses" of childhood, see below. Heine-Medin diseases is also an occasional cause.

†It is probable that in some cases the entire pathological process consists in "edema" which goes no further—and finally clears up. Brain edema, however, brings up a very complicated subject. It will be discussed in a later chapter of this study.

cysts. The skull over such affected area may show depression, and is usually smaller on the side of the lesion (opposite the paralyzed side), and sometimes is smaller all around (microcephaly).

Prognosis and Course.—The prognosis in encephalitis is serious, yet by no means as serious as in meningitis—and recovery is frequent. Where recovery sets in, the progress is rapid; occasionally, however, it is slow over a period of weeks or months. The aphasia most often clears up, the paralysis or paresis shrinking in area. Occasionally the hemiplegia disappears, leaving a hemiparesis in its wake. Once in a while a case—even if of severe type—completely recovers. More often, however, a permanent spastic hemiplegia results. The convulsions occurring early in the disease may persist, or, after ceasing over an interim of weeks, months, even years, may again appear as an epilepsy not distinguishable from the "genuine" type. Rarely it is of Jacksonian form. Convulsions may obtain even where no paralyses exist. Rarely, too, blindness or hemianopsia remains as a residual. Hearing seems scarcely ever affected. Starr[33] mentions however that word-blindness or word-deafness may prove a residual and be the origin of deaf-mutism in some cases. The more extensive the involvement, and especially the earlier the disease, the greater is the likelihood of mental enfeeblement due to focal destruction of brain tissue and resulting diaschisis, and particularly inhibition of general brain growth.

60 WEST EIGHTY-FIFTH STREET.

THE INTENSIVE TREATMENT OF HAY-FEVER.

BY WILLIAM SCHEPPEGRELL, A.M., M.D.,

NEW ORLEANS.

PRESIDENT AMERICAN HAYFEVER PREVENTION ASSOCIATION; EX-PRESIDENT AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY.

As the season for the immunizing treatment of fall hayfever is at hand, it is well to consider the principles upon the proper observance of which successful results may be expected.

True hayfever is caused by the anaphylactic reaction from inhaled atmospheric pollens. These pollens vary in different localities, at various seasons, and in their degree of reaction upon susceptible subjects. The result of these variations is that hayfever presents complex conditions, differing from other diseases due to some specific cause.

Some manufacturers of pollen extracts, apparently not taking cognizance of these factors, have attempted to simplify the immunizing methods by preparing mixtures containing the most common pollens. Many of these contain not only pollens responsible for hayfever, but even some that, for various reasons, the patient never has an opportunity to inhale.

The result of this "shot-gun" method is that the

patient usually receives an injection containing a mass of inert protein that leaves the possibility of benefit very doubtful. On the other hand, the patient may have an unusual degree of anaphylaxis to a number of the contained pollens, the result of which is that the injections produce a profound reaction detrimental to the patient. In some of the circulars with these mixed pollen extracts, it is even stated that no diagnostic tests are required, all that is needed is to inject the specified doses!

Any physician with experience in hayfever cases, has observed the great difference in the intensity of the symptoms, and in the reactions to the diagnostic tests. In some cases, the injection into the skin of 5 units will produce a positive but mild and transient reaction, while in others the same number of units will produce a wheal three centimeters in diameter, and surrounded by a wide area of injection, and lasting for many hours.

In the former, with a low degree of anaphylaxis, the doses may be increased with comparative rapidity and safety, and must reach a high number of units in order to be effective.* In the latter, however, the increase must be made cautiously, and the maximum dose carefully determined. In a number of our cases of high intradermal reaction, an injection of 200 units will invariably develop an attack of hayfever, or skin eruption, while in others a dose of 500 units reached by gradual stages, will produce no apparent reaction.

Another point of importance in the successful treatment of hayfever is to remember that all fall hayfever patients east of Kansas are not necessary victims of the Ambrosiaceæ (Ragweed) Group, or even if this is the case, that this is the only cause. In a large area of the North Eastern States, for instance, the Russian thistle, *Salsola pestifer*, is a potential cause of hayfever infestation, that should be carefully considered in the successful treatment of these cases. This is especially important, as these cases do not respond to the diagnostic tests of the Ambrosiaceæ group and are not benefitted by the injections of these pollen extracts.

The successful results obtained by physicians following scientific methods in the diagnosis and treatment of hayfever, has resulted in a great stimulus in the immunizing treatment of this disease. If the "extensive" methods are followed, however, in which no diagnostic tests are made and no cognizance taken of the varying degree of sensitivity and the different kinds of pollen involved, the results will be disappointing to the patient and an apparent reflection on the immunizing method.

The intensive method, however, in which all the factors bearing on each individual case are carefully considered, will not only give satisfactory results to the patient and physician, but will place this method on the scientific basis to which it is entitled.

METHOD OF PROCEDURE IN TREATMENT OF CASES OF DOUBTFUL INITIAL LESION.

By ARTHUR SAYER, B.S., M.D.,

NEW YORK.

CHIEF OF CLINIC IN DERMATOLOGY AND SYPHILIS, MT. SINAI DISPENSARY.

In the large majority of cases, the physician with experience in syphilis is able to recognize without difficulty cases of chancre which present themselves to his attention. In cases of well-developed initial lesion, he can make a diagnosis on clinical grounds without the aid of the laboratory (dark field examination or Wassermann test). The indurated character of the lesion, the characteristic enlargement of the regional lymph nodes, perhaps the presence of a cutaneous eruption with general adenopathy—all these are criteria upon which the diagnosis of initial lesion may be made with certainty. In such cases the indications for treatment are evident, and the institution of vigorous antiluetic tretatment even before a positive dark field or Wassermann report is obtained, is certainly indicated. We are sure of the specific nature of the disease on our clinical grounds, and the laboratory can give us only confirmatory proof. The Wassermann test is made not so much for diagnosis as for prognosis, and as a matter of record in such frank cases.

Occasionally, however, a person may present himself with a penile lesion which is not at all characteristic. Perhaps it is a chancre of only one or two days' duration which has not yet assumed its characteristic induration, and adenopathy is not yet present. Or, as often occurs, the lesion is not luetic and is merely under suspicion on account of its location or on account of a history of exposure to infection. Lesions of herpes progenitalis, chancroid, and even scabies will occasionally cause anxiety on the part of the patient and doubt in the mind of the physician as to the true nature of the lesion. We must, of course, regard all penile lesions with extreme suspicion of being luetic until it is definitely proven otherwise, since we frequently see doubtful lesions which are subsequently proven to be chancres.

Of course in all doubtful cases we have positive criteria for diagnosis at our command—the dark field examination of the lesion and the Wassermann test of the blood. We recognize the limitation of the Wassermann test, however, as an aid to early diagnosis, since it is still negative in the majority of cases of early chancre. Nevertheless, the test should repeatedly be performed in all doubtful cases, as it may in some cases be positive while other tests are still negative. The dark field examination is the only aid we possess for the *earliest* detection of the chancre, since the finding of the spirochete is absolute proof of the nature of the infection. The dark field examination should be made repeatedly on all cases which are in the least doubtful clinically. A negative dark field is not conclusive proof of the nonluetic character of the lesion; it means that more examinations should be made until the findings are either positive or the nonluetic character of the lesion otherwise proven. Often the patient will present him-

self with a penile lesion which has been treated locally with antiseptic (calomel or bichloride); such lesions will usually give negative dark field findings on account of the spiricidal influence of the local treatment. We should, therefore, strongly advise against the use of local treatment other than saline solution in all cases which are to be examined by the dark field. If the lesion is luetic the dark field will prove it in the vast majority of cases, although several examinations may be necessary before the spirochetes are finally found.

In such doubtful cases where the dark field examination is negative on one or two occasions, the physician is often placed in a peculiar mental attitude as to his responsibility to the patient. He knows that the lesion may be luetic in spite of the negative findings to date. He knows that the sooner vigorous antispecific treatment is instituted in a chancre the better are the pattient's chances for being cured of his syphilis. He also realizes that by waiting until the dark field or the Wassermann is positive he is losing time, and that meanwhile the spirochetes are multiplying in the lesion and continually invading the lymphatics and blood stream. He may also argue that little harm will be done to the patient by giving him several injections of salvarsan and mercury, to subject the lesion to the therapeutic test, and if it responds favorably to the treatment, then to assume that the lesion was luetic and treat the case accordingly. Also the physician may say that should the lesion not respond to the treatment and later prove nonleutic, then the patient is none the worse for his experience.

The writer believes that such a procedure is not proper, for he has seen several cases of doubtful type of penile lesion in the past few years which have been subsequently proven to be nonluetic. It has been strongly impressed on my mind that the conservative course is the proper one to follow—to withhoold all treatment until a positive diagnosis has been made. It is unfair to stigmatize a person with the taint of syphilis until we have acquired absolute proof as to the undoubted nature of the infection. It is far better for the patient's future welfare and happiness to determine definitely the nature of the penile lesion by repeated examinations than hastily to institute antiluetic treatment in a desire to arrest the course of a doubtful syphilitic infection. Should the lesion heal while under the antispecific treatment, that is not absolute proof of the luetic nature of the lesion, since non-specific lesions will often heal spontaneously and irrespective of the treatment instituted.

It has been proven that the lymphatics are invaded in the earliest stages of the chancre and the disease is already systemic by the time the initial lesion has developed. It is therefore manifestly impossible to abort the course of the disease by instituting vigorous treatment when a primary lesion is already noticed. The physician can well set aside his fears and make sure of his diagnosis before instituting any sort of treatment. It will make no difference as to the course of the disease nor alter the prognosis in any way to wait a few days longer, during which time the diagnosis can be determined.

We are not absolutely sure that we can cure syphilis with salvarsan and mercury, although we are certain of the extreme potency of these drugs in this disease. Our criterion for the cure of syphilis is a persistently negative Wassermann (both blood and spinal fluid). Yet a repeatedly negative Wassermann is not absolute proof that the disease has become eradicated from the system and that the last surviving spirochete in the tissues has been killed. We must keep our patient under observation for the rest of his life, taking periodic Wassermanns to make sure that he remains serologically negative. Occasionally a person who has been treated in an approved manner will be serologically negative for several years, and suddenly give a positive serological report, which indicates that the disease is still present in the system and requires further treatment.

Did he have a syphilitic infection which was arrested while still in its early stage, and which is remaining dormant in the body? In other words, is he cured of his syphilis? Shall he continue taking periodic antiluetic treatment in order to keep the syphilitic infection under control? These are the questions which the intelligent patient will continually ask, and which the physician will be unable to answer definitely. We will, therefore, condemn needlessly a patient to a state of anxiety and doubt, merely because of an unwarranted haste in instituting treatment for which we had no positive indications.

It is, therefore, for the best interest of the patient, in all cases of doubtful initial lesion, to be sure of the diagnosis before commencing treatment. The doctor need have no hesitancy in delaying antispecific treatment, for the prognosis will be the same if the case is treated properly subsequently. By delaying treatment in doubtful cases until the dark field is positive or the Wassermann is positive, some errors will be avoided and a lesion will often be proven to be other than a chancre. The dark field examination will be positive in all cases of chancre which are not treated locally with antiseptics, and three to five examinations will no doubt find the spirochete even in the most troublesome of cases. An effort should be made to find the bacillus of Ducrey, either by direct smear or culture in these cases, for the chancroid may in some cases simulate the chancre very closely. In herpes progenitalis there are usually one or more vesicles which disappear in a few days; the bases of the vesicles are not indurated and there is no glandular involvement present. Strange as it may seem, occasionally a case of scabies may fool an experienced observer. The penile lesion may be the only one noticed, and the patient give a history of exposure to venereal infection. Further observation of the case, however, will reveal the presence of other scabetic lesions (in the webs of the fingers, axillæ, around the umbilicus) and the person later complains of itching.

The following history illustrates this point.

Case 4469.—H. K., 23 years of age, presented himself on February 6, 1921, at the Mt. Sinai Dispensary, with a penile lesion near the meatus. The lesion was about ½ cm. in diameter, and was not indurated in any degree. The patient gave a history of having had intercourse with a prostitute six weeks ago while on a visit to France. In view of the history of the exposure,

a tentative diagnosis of either chancre or herpes was made. Dark field examination was not done, as unfortunately we have no dark field apparatus at our disposal in the clinic. The Wassermann was reported negative. The patient returned two days later for observation and no difference was seen in the lesion. Another Wassermann was made and was still negative. On Feb. 11 the Wassermann was repeated, wtih the same result as before. At that time the right lip of the urethral meatus appeared to be indurated and the lesion began to look somewhat like a chancre. However, the inguinal adenopathy was not characteristic. On February 14 the patient presented himself again. On careful examination two burrows were seen in the webs of his fingers. No other lesions of scabies were present. The patient admitted that he had a slight itch at night. A salve containing 10 per cent. sulphur and 10 per cent. balsam of Peru cleared up the penile lesion in two days, and the rest of the scabies also disappeared under the treatment. Since then two Wassermanns have been negative (the last one on March 4, 1921).

957 SIMPSON STREET.

ON COLLABORATIVE DIAGNOSIS.

BY JACOB GUTMAN, M.D., Phar.D., F.A.C.P.,

BROOKLYN, N. Y.

DIRECTOR, BROOKLYN DIAGNOSTIC INSTITUTE.

LIKE the metamorphosis of the butterfly, which consists in a periodic casting off of certain parts in order that the succeeding ones may obtain their highest state of evolution, the art of healing, as at present practised, is the perfected outcome of the wisdom of the ages developed by special talent. Each succeeding discovery has revolutionized some hitherto accepted principle in medicine. The elaboration of synthetic chemistry and analytical laboratory methods, the perfection of *x*-ray diagnosis and of serologic, bacteriologic and other delicate tests, have made it necessary to discard many principles heretofore regarded as basic, or to modify them to such a degree that their identity is completely lost.

As the scope of the medical art increased it became necessary to divide it into specialties. Specialization is a step forward along the road to perfection, for it stimulates research and encourages advancement in every branch of medical science. The next step leading toward even greater individual perfection was the limitation of activity to only one section of the special field. Today it is by no means inevitable that a tissue morphologist should likewise be an expert bacteriologist, nor a biochemist be capable of exactly interpreting any problem in pathology or bacteriology. Formerly the pathologist attempted to perform all these functions of diagnosis, but today specialization is a recognized factor and is everywhere demanded. The specialist has rendered invaluable service, deserving even greater recognition than he has already received. The hospital, the clinic, the family practitioner, come to him for aid, even the layman and the corporation are seeking his services.

Correct diagnosis, even under the best conditions, is difficult to attain; though all the facilities may be at hand, there are times when even the most experienced may go astray. This is admitted by the most renowned clinicians. Every physician should be capable of handling the average pathological problem; but when simple manifestations assume a chronic form, refusing to be easily eliminated, it is time to realize that the situation has ceased to be an ordinary one, and that more obscure causative factors are responsible for the patient's condition. But until these underlying causes are revealed and removed, no progress can be made toward relieving the symptoms and facilitating recovery. It is then that special talent and expert diagnostic ability are needed.

The secret of successful therapy lies in early diagnosis. There is a time when cancer may be operated upon, but there is also a time when it is too late for operation. The successful treatment of incipient tuberculosis, of obscure infections or visceral disturbances depends entirely upon the *early* recognition of the existing condition. The surgeon has an advantage over the internist, for he can make an incision, inspect and palpate the organs thus exposed, and by this means establish a diagnosis; yet exploratory operation is only justified in the most baffling and obscure cases, when every other means of research has proved of no avail.

The determination of a patient's true condition can best be established when studied jointly by several capable specialists. But usually this method of diagnosis is practical only in a well-equipped hospital or special diagnostic institution. Medical science is today a vast subject, too great for any one man to master. It is impossible for any one person to make use of all the apparatus of its manifold specialties, even in the most superficial fashion. In former times, when the field of medicine was very narrow, anyone of sound intelligence could practise it efficiently, but today, with the advent of epoch making discoveries and the stupendous progress which science has made in recent years, the practice of medicine has become a very difficult task. To claim a knowledge of every branch of the healing art, is to put in jeopardy the welfare of all who trust in the skill and wisdom of him who makes the profession; the fallacy of such a pretension will soon be made evident, and the man who makes it quickly exposed and discarded.

Judging by the progress it has made in its short period of existence, and the good it has already accomplished, the future of group diagnosis appears to be very bright. The fact that the foremost medical centers have hastened to avail themselves of this practise speaks eloquently for it. The highest function of medical science is to restore health to the suffering. The most efficient means enabling one to do this quickly and completely is a precise knowledge of what is going on in the deranged organism, that is, correct diagnosis. This is the ultimate goal for the physician, inasmuch as therapy wholly depends upon it and cannot be successfully applied without it. The attainment of this goal is the function of the diagnostic institution.

The subject of group practice has recently been much discussed. Extensive consideration has been given to its advantages and drawbacks, its prospects and methods of organization, its ultimate effect upon the present system of medical practice. Thus is displayed the present very great interest in this exceedingly material question. In an article entitled "Group Diagnosis," published in the MEDICAL RECORD May 15, 1920, the author has already fully expressed his theoretical views on this subject, and he has given practical support to his contentions by

the organization of a diagnostic institution. Progressive physicians, alive to the possibilities of group diagnosis, have already expressed the approbation by availing themselves of its services. The medical man, on the alert to render to those dependent upon his skill and judgment the very highest quality of service, utilizes this aid to diagnosis whenever it comes within his reach, or gladly lends a helping hand in its organization wherever no diagnostic institution is in existence. Such organizations were inevitable. The inefficiency of the present system of individual diagnosis constantly becomes more conspicuous when compared with the quality of the work done in clinics where group diagnosis is practiced. That there is a great movement on hand in the direction of organization of institutions of this character may be concluded from the many inquiries received by the author. May good fortune attend every effort in the promotion or advancement of correct diagnosis!

867 St Mark's Avenue.

TWO CASES OF ADVANCED SUPPURATIVE DISEASE OF LATERAL SINUS AND JUGULAR VEIN.*

By CHARLES E. PERKINS, M.D.,

NEW YORK.

SURGEON NEW YORK EYE AND EAR INFIRMARY, ETC.

Case I.—This case came under my care in Base Hospital No. 116 in France early in January, 1919. The patient, a man of about twenty-six, had had suppurative otitis media on the right side for about two weeks. The canal was filled with creamy pus, the mastoid tender, the temperature over 102°, and he looked sick. I asked for medical consultation. The examiner pronounced it pneumonia and removed the patient from my service to the medical side. At the request of the medical attendant, I saw the patient at two or three day intervals during the next ten days. The temperature fluctuated between 99° and 103° to 104°, and to relieve my anxiety at this symptom I was assured that this temperature curve was characteristic of the pneumonia prevalent in the army at that time. Cultures of the blood were negative. The patient developed a tender swelling in the neck on the right side, which increased in size and became red. The aural condition improved, and the mastoid tenderness became less and finally absent; but his general condition grew progressively worse. In fact, to my suggestion that an *x*-ray be taken, it was declared that he was too weak to be moved to the *x*-ray room. However, when his temperature made a sudden rise to 107° I was given a free hand to go ahead.

The jugular vein was resected. It was very much thickened and the upper end was broken open, communicating with an abscess in the neck. At the lower end it was cut between two ligatures just above the clavicle. At this point the vein contained a clot. The mastoid was but slightly diseased except for a perisinus abscess. The lateral sinus was incised and bleeding obtained from the torcular end, but not from below.

The patient made a stormy convalescence. Pain, swelling, and stiffness developed in both shoulders, and he remained very sick for three weeks, but finally recovered. The operation wounds healed in about one month. Two months after operation, while he was strong and well, the movement in both shoulder joints was very much impaired.

Case II.—The second case was that of a girl six and a half years old, who came under my care January 30, 1921. Six weeks previously she had acute otitis media on the left side. This lasted for two weeks without apparent complications, when the discharge ceased. She then developed characteristic attacks—chill, followed by rise of temperature to 104°-105°. These continued daily, or twice a day, for four weeks. On one occasion only was there a free interval of one day. A vigorous search was made for the cause of the infection—kidneys examined, chest *x*-rayed, malaria sought for, etc. Blood culture finally showed the presence of *Streptococcus hemolyticus*. There was a division of opinion among the attendants in regard to the treatment, the majority, I think, favoring jugular resection.

At my first examination the ear was dry, with lustre returning to the tympanic membrane. The hearing was good. There was no mastoid tenderness or thickening in the neck. The blood culture was negative, spinal fluid, negative. The *x*-ray plates of the two sides taken by Dr. Dixon showed changes on the left side which were interpreted as produced by diseased mastoid, so operation was determined upon.

The mastoid was broken down in the sinus region and the cavity was filled with granulation tissue; no free pus. The removal of the granulations brought the sinus into view. It appeared red and thickened. It was freely exposed, blocked off, and incised. It contained no clot or pus but was collapsed. Bleeding was obtained from the torcular end. A grooved director passed into the jugular bulb brought a free flow of pus. No attempt was made to open the mastoid antrum or tympanic vault, as resolution had occurred in this region. The lower part of the jugular from the omohyoid upward for about half an inch contained blood coming from an anterior branch; above this it was thickened and contained pus. Upon passing the grooved director upward through the vein to the bulb a large quantity, comparatively speaking, of pus escaped. This contained an abundance of long-chained streptococci.

The patient had two rises of temperature to above 104° after operation, and then a more or less irregular temperature. From the fourth week on it was normal. In the beginning of the third week the right shoulder joint became tender and somewhat swollen. This lasted for about a week and then cleared up, leaving the function apparently normal. The neck wound healed in three weeks, the mastoid wound in six weeks. The ear remained dry throughout the convalescence.

These cases are exceptional in that a late operation was done. In the first, a swelling in the neck with breaking down of the jugular had occurred in less than fourteen days; while in the second, after four weeks the pus resulting from the breaking down of the clot was still contained in the vein.

When the first case was related to Colonel McKernon he stated that the late Doctor Gruening had claimed that he had never seen a patient recover when in resecting the jugular vein it was found impossible to tie below the clot. In my patient the vein at the clavicle was as large as one's little finger, with thick walls and a distinct clot was left extending toward the heart.

Another point is that in the second case no attempt was made to open into the middle ear. In the right type of case I have adopted this variation and have had no cause to regret it. In some patients the infection passes through the middle ear, which then becomes walled off, the breaking down of bone occurring in the mastoid, while resolution takes place in the middle ear spaces. In such instances, after removing the disease in the mastoid, it is worse than useless to open up the middle ear and thereby aid in its reinfection. By desisting from this, certainly hearing should be conserved and convalescence shortened.

THE PATHOLOGY OF MALIGNANT TUMORS OF THE HEART.

OF primary malignant tumors of the heart myxomata have a predilection for the left heart, especially the left auricle, where the growth is implanted usually at the posterior portion, at times near the left wall, at other times above the line of insertion of the anterior lip of the mitral valve. Sometimes the growth becomes engaged in the mitral orifice, producing dilatation of the auricle. Myxomatous neoplasms will be either somewhat round products or else are pedunculated. The pedicle is rather long, single or multiple. The growth may be single or composed of cotyledons which give it the look of a bunch of grapes. In size these neoplasms vary from that of a cherry-stone to a pigeon's egg, pale red in color, while occasionally ecchymotic points may be seen. Their consistency is like jelly, the surface smooth and shiny, but often covered with an adherent thrombus. Histologically, these primary neoplasms are composed of round or fusiform cells comprised in a semi-liquid transparent mass. Numerous elastic fibers may sometimes be met with. Sarcomatous growths may involve the entire heart or develop in a ventricle or auricle or in both at the same time. They are subpericardial, intramyocardial, or endomyocardial. There are several histological types, namely, lymphosarcoma, roundcell or fasciculated sarcoma, and also fibrosarcoma.

Secondary malignant cardiac growths are seated in either the ventricle or the auricle. They may involve both auricles or both ventricles at the same time, or the right or left heart may be the seat of the neoplasm, but it has a predilection for the right side. The neoplasm may infiltrate the entire myocardium in some cases. These growths are present in the form of nuclei projecting under the pericardium or endocardium or they may be interstitial. In other cases the cancerous mass surrounds the heart, pericardium, and vessels at the base of the organ, or the growth may form a tree tumor, rarely ulcerated, projecting into the cavities of the heart. Usually the valves are intact.

Secondary malignant cardiac growths may be divided into two types, namely, epithelial and sarcomatous, and since these secondary neoplasms may be derived from any part of the body if therefore results that all anatomical forms may be met with. The epitheliomata are composed of cylindrical or pavement cells with a connective tissue stroma, forming meshes filled with epithelial elements. A large number of leucocytes will be found at the periphery of the tumor and if suppuration occurs they will be present among the epithelial cells. The sarcomata are round-cell, fusiform cell, or polymorphous. Their substance contains numerous vessels, many being partially thrombosed. Lymphosarcoma, melanic sarcoma, and sarcoma with myeloplaxes are also met with. Lymphadenic growths, without hemorrhagic foci, sometimes develop in the heart, and are thus differentiated from all types of carcinomata. The portions of the heart involved appear to be infiltrated with an enormous quantity of round cells with a large nucleus almost filling them. These cells form cords around the normal vessels of the region.

A cancerous heart is larger than normal, especially in the parts involved, but when the interstitial cancer nodules are very small inspection shows nothing abnormal about the organ. The heart may, however, present well developed vascular arborizations. The muscular fibers are whitish-yellow and on sections the wall involved by the growth is seen studded with whitish-yellow islands. At some spots granulations may be seen on the pericardium, which are nothing but the cancerous prolongations reaching the surface of the organ. In most cases the pericardium contains a transparent or hemorrhagic fluid collection.

When the pathological tissue dips down into the myocardium and reaches the internal surface of the heart underneath the endocardium, it looks like small white specks. The process spreads out in the thickness of the walls over quite an extensive area. If the growth projects into one of the valvular orifices, dilatation of the auricle ensues and usually of the ventricle as well. Microscopically the muscle cells are piled together and pushed aside but are not destroyed by the neoplasm. Occasionally the cardiac muscle cells are necrosed and undergo disintegration, forming small oval masses with distinct outlines. These masses, composed of a granular or amorphous substance staining with eosin, may also form long tracts which interlace among themselves, outlining a network of narrow meshes filled with sarcomatous cells.

FUNCTIONS OF THE PINEAL GLAND.

ZANDRÉN contributes a short but monographic study of this subject to the *Acta Medica Scandinavica*, liv, 4, with a bibliography of thirty classical references. The subject goes back to Galen who criticised adversely the views of the day and substituted his own, which persisted up to the time of Descartes who regarded the gland as the seat of consciousness and personality. No rival opinion to this was hazarded until the time of Faivre who

made the first thorough histological study and thereby inaugurated a series of similar studies, so that the anatomy of the organ was mastered. The first physiological study which led to the belief that the organ regulated the pressure of the cerebrospinal fluid was supplanted by that of Marburg and von Frankl-Hochwart which is that it is a gland of internal secretion. Animal experiment has not contributed to our knowledge. The results of pineal feeding are negative in part, although persistent injection of gland substance in the immature animal has seemed to hasten the development of puberty. Extirpation of the gland is technically difficult and no trustworthy results have been obtained from this resource. In some cases results have actually been the same as those of gland feeding. This constitutes a *reductio ad absurdum* and we have to resort to the study of pineal tumors of which about 70 are now on record. In sexually mature men the results are limited to intracranial pressure symptoms, but in young boys there is at times induced in addition the condition known as macrogenitosomia precox. Sexual development, both primary and secondary, is hastened; the external genitals are large, and there is an abundant growth of pubic and axillary hair, with deepening of the voice, etc. Precocity, mental and somatic, is sometimes present. Data for the female sex are lacking, for apparently there has never been any autopsy confirmation of the diagnosis. The significance of these tumor cases has been slightly weakened by the possibility of lesions of other endocrine glands.

The syndrome of pineal tumor does not cover that of precocious puberty in which the gland may be normal. Opinion is divided as to whether the pineal cells stimulate or inhibit puberty. If the neoplastic process destroys the cells the withdrawal of their influence would cause some other structure to stimulate puberty unchecked. If as a result of the neoplastic process there is an increase in the pineal cells, or if the latter are unduly stimulated, then the pineal body must be visualized as the normal stimulus to puberty. The weight of opinion is decidedly in favor of the inhibitory theory. The author reports what he believes to be a unique case of pineal infantilism in which there was total defect of the gland. The boy was normal up to the prepuberal years, when he not only ceased to grow but became an invalid. At the age of nearly 17 he presented the picture of a boy of 12. His chief symptom was marked anemia, which was doubtless responsible for the other symptoms. Death was thought to have been due to perforation of a gastric ulcer, but nothing of this sort was found at autopsy. Of great importance was the find of a normal thyroid. The tests corresponded histologically to those a year-old baby. The author's case seems to antagonize the inhibition theory. In the absence of a pineal body the testes should have developed early. The statement that the pineal gland regresses at puberty is denied by Krabbe.

All recent writers on this subject ignore the presence of the brain sand in the pineal body; yet there must be some significance in the fact that its presence and abundance seem to bear some relation to the mentality of the individual, there being but little or none in infants and idiots. It might be worth while for those who are collecting data as to the weight, the number of convolutions, etc., of the brains of men of intellect to weigh the acervulus in order to determine the relationship, if any, between its amount and the degree of intellectuality. We may some day be able to manufacture geniuses by feeding the young with triturations of pineal sand.

CAPILLAROSCOPY.

By this term one understands the study of the capillary circulation. It may thus be said to go back originally to Malpighi, who studied the capillary circulation in the web of the frog's foot at a remote period. Lombard of the United States studied the skin capillaries after first making that structure more translucent with oil or glycerin. This physiologist even devised an ingenious apparatus to measure the blood pressure in the capillaries. Some years later (1916) Müller and his pupils in Tübingen devoted much time to erecting a system of capillaroscopy in its application to normal and pathological physiology. Policard in France took up this study which he termed microangioscopy and articles appeared in Great Britain and Italy as well.

In a review of the subject in *La Presse Médicale*, xxix., 11, Weiss, after a summary of the pioneer work of Lombard, discusses at some length the effect of this study upon our knowledge of physiology. Apparently the respiratory movements play a considerable role in advancing the blood through the capillaries. The view is of course by no means new but capillaroscopy goes far to uphold it. The evidence cannot be brought out in normal conditions, but in asystolia the part played by respiration is plainly manifest. The part played by compressing the arm is dealt with at length but conditions here are artificial. It is, however, at the foundation of many induced phenomena which can be studied in the capillaries.

In regard to pathological states those first studied were dermatological and data have been isolated concerning the peculiarities of the capillary circulation in scabies, scleroderma, the exanthemata, etc. There have been some striking finds, such as the ability to recognize the participation of the kidney in scarlatina from the appearance of the skin capillaries. The close correspondence between the minute vessels of the two organs for the first time suggests that scarlatina is to be regarded as an affection of the blood-vascular system.

Next come the data isolated for diseases of the heart and large vessels and especially affections of the extremities such as Raynaud's disease; chronic alcoholism; saccharine diabetes; acute nephritis, other than scarlatinous; chronic interstitial nephritis, etc. The enthusiasm on the part of students of the new art is very great and doubtless

much will be over-emphasized. It does not appear that any diagnoses have been made by this resource unaided, despite the fact that the capillary behavior of many affections may be individualized. Neumann, the latest and most enthusiastic worker to publish his finds, lays stress on the value of the new resource because it enables us to study the pathology of the capillaries themselves.

Post Influenzal Psychoses.

An attack of grippe probably gives rise to more psychoses than any other disease. After influenza the mind is frequently affected to a greater or less extent and psychopathic manifestations of various kinds and degrees of severity are very common. Dr. E. Gay of the University of Toulouse in a thesis referred to by the Paris correspondent of the *Medical Press and Circular*, June 15, 1921, has described the psychoses which had been observed after an attack of grippe: (1) Asthenia has been the most frequent and characteristic symptom during the convalescence of influenza. It was accompanied by very marked moral, intellectual, and physical depression. (2) Delirium was also very frequent in the form of acute delirium with excitation and hallucinatory syndromes. (3) Mental confusion. (4) Melancholia with tendency to suicide. (5) Delusion of persecution, the patient taking the neighboring patients in the wards for spies or complaining that the physician has not been treating him properly. After recovery the patient remembers nothing of these delusions. (6) Obsessions and impulsions. (7) Hysteria. It will be thus perceived that Dr. Gay has observed all varieties of psychoses, the most frequent, however, seeming to be hallucinatory delirium with excitation in general. The prognosis is good and depends much more on the mental constitution of the patient than on the intensity of the influenzal infection, for if there can be no doubt that the influenzal virus may determine the appearance of a psychosis, in the great majority of cases the latter is favored by a neuropathic or psychopathic predisposition. It appears a reasonable supposition that psychoses follow influenza only when the patient has a tendency in this direction. The individual absolutely mentally well-balanced is not likely to develop a psychosis after an attack of influenza and the frequency of this development may, perhaps, be rightly regarded as evidence of the large number of persons who are not perfectly balanced mentally. Of course, the further the mental balance deviates from the normal, the more seriously will the patient in this condition suffer from psychosis. Influenza possesses the sinister faculty of finding out the weak points in a person's armor of health be they mental or physical.

An Editorial Experiment.

The initial number of *The International Journal of Gastro-Enterology* appeared the first of this month under the editorial management of Dr. A. L. Soresi of this city. It contains thirteen articles, classified under the heads of Original Communications, Experimental Medicine, Reports of Interesting Cases, Preliminary Notes, and Monthly Review. One of the articles is in Italian, one in French, and the others in English. They are all valuable contributions of variable degrees of interest, some practical, some purely scientific. The editor has certain definite ideas as to the management of his journal which he may succeed in putting into execution. One of these is the publishing of commentaries or criticisms on the original articles, these being written by men to whom the editor has sent the article in manuscript or proof with the author's name withheld. The author, if he objects to any of the commentaries, will have the privilege of replying in subsequent issues. Another innovation is the division of papers into original communications and preliminary notes. Under the first head will appear papers containing "fully developed ideas original with the authors." When the editor is of the opinion that "the communications do not develop fully the ideas expressed by the authors," the papers will be relegated to the department of preliminary notes. Already the editor has had trouble with his contributors through his insistence on these two points, but he is undaunted thereby and expresses his determination to edit his journal along these lines. It will be interesting to see what success he has. But in the meantime he has published one very commendable issue, and if the subsequent numbers carry out the promise of the first his journal will deserve the success which it will no doubt then attain.

News of the Week.

Cholera Rages in Moscow.—The Moscow *Izvestia* reports the registration up to July 13 of 27,779 cases of cholera, as compared with 13,476 registered up to July 6. Among passengers on railway trains 5,412 cases have been discovered. Small numbers of cases have been found all the way from Petrograd to Astrakhan, from Vitebsk to Petropavlovsk, near the Omsk, and along the principal lines of railway and water communication. The health officials of Letvia, Esthonia, Lithuania, and Poland have been invited by the Letvian Premier to a conference at Riga to discuss the advisability of a frontier quarantine.

Maternity Bill Passes Senate.—The Sheppard-Towner bill, providing for cooperation between the Federal Government and the States in "the protection of maternity and infancy," was passed by the Senate by a vote of 63 to 7 and sent to the House on July 22. An effort to have the administration of the service provided for by the bill transferred to the Public Health Service failed. The bill carries initial appropriations of $1,480,000, which, if the bill becomes law, the States will be required to match if they wish to suffer from it.

A Survey of Mental Disease.—A survey of mental disease in the United States shows that on January 1, 1920, there were 232,680 persons with mental disease in institutions in the United States. Of these 40,515 were mental defectives, 14,937 epileptics, 1,163 alcoholics, and 808 drug addicts. In the hospitals of New York State there are 38,903 patients, of whom 5,762 are mental defectives, 1,683 epileptics, 67 alcoholics, and 156 drug addicts. These figures are interpreted as meaning

that out of each 100,000 population in New York State 374.6 are afflicted with mental disease and 55.5 are mental defectives. The most recent survey of Sing Sing prison shows that more than 50 per cent. of the inmates are not normal mentally, and that of 166 women brought into the courts 61 were mentally only children. The report also shows that, while the population of the United States had increased 14.9 per cent. during the decade from 1910 to 1920, the number of patients in institutions for the mentally ill has increased 23.9 per cent. To discuss this report, which was made by Dr. Augusta Scott, a meeting of judges, physicians, and welfare workers met recently at the residence of Mrs. E. H. Harriman. After going over the problem it was the consensus of opinion that court methods should be changed. Dr. Walter B. James contended that mental examinations were indispensable in the proper handling of criminal cases, and Chief Justice Kernochan advocated a central bureau supported by the city with experts in charge for the examination before trial of all persons charged with crime.

Intensive Study of Rickets Planned.—The *Weekly Bulletin* of the New York Department of Health announces that for the purpose of formulating a program for a study of rickets to be conducted by the Bureau of Child Hygiene of the Department of Health and the Association for Improving the Condition of the Poor, a special committee met in the office of the Director of the Bureau of Child Hygiene to discuss the details of the plan. The proposed observations will be carried out in the Mulberry Health Center, located in the Italian district, Broadway, the Bowery, Canal, and Houston streets. The aims and purposes of the study are, first, to ascertain the prevalence of rickets among children born of Italian parentage, in those nursed exclusively and in those fed artificially; second, to prevent rickets by various measures, such as the use of cod liver oil, sunlight and fresh air, diet, hygiene, etc.; third, by the use of cod liver oil to cure the condition after it has appeared. The committee is composed of the following: Prof. H. C. Sherman, Prof. Mary S. Rose, Prof. Graham Lusk, Dr. Alfred F. Hess, Dr. Charles Hendee Smith, Dr. Louis Schroeder, Dr. J. M. Blumenthal, Mr. Bailey B. Burritt, Mr. John Gebhart, and Dr. Jacob Sobel.

Malnutrition in School Children Shows Decrease.—In a recent review of the results attained through school medical inspection, the New York City Department of Health shows that the striking increase in malnutrition among children of school age, which began to manifest itself in 1914 and reached its apex in 1917, has since then shown a slight but regular decline. During the year 1919, with the cooperation of the Department of Education, the Bureau of Child Hygiene made 51 special surveys of public schools where it was felt that conditions were below the average standard. It was found that the number of malnourished children in these schools ranged from 13 per cent. to 61.4 per cent. In 1920 the Bureau made surveys on 63 schools, where the number of cases of undernourishment was found to range from 8.9 to 36.3 per cent. The schools covered in the two years were practically the same, showing that the work which had followed the surveys had proved effective in markedly lowering the rate of malnutrition in these schools. The Bureau of Child Hygiene feels that the solution of this problem of the undernourished child cannot be brought about by the provision of any facilities, however adequate, for dealing with children who are already undernourished. The program must be based upon preventive lines similar to those that have been effective in baby-saving work.

Hartley Foundation Incorporated.—The Hartley Foundation, consisting of several million dollars given by Mrs. Helen Hartley Jenkins, in memory of her father, has recently been granted a special charter by the Connecticut Legislature. The foundation will give special attention to public health, mental hygiene, and probation work. At a meeting held in Hartford, Conn., July 20, the following officers were chosen: *President*, Mrs. Helen Hartley Jenkins; *Secretary and Treasurer*, Robbins B. Stoeckel; *Executive Committee*, Governor Everett L. Lake, Miss Helen Hartley Jenkins, daughter of Mrs. Jenkins; Dr. Samuel A. Brown, New York, and Marcellus Hartley Dodge of Bridgeport. Among the incorporators are Dr. Thomas W. Salmon, Dr. Herman M. Biggs, Charles M. Schwab, and James Earl Russell of New York.

The New York Association for Medical Education announces through its secretary, Dr. Otto V. Huffman, that the Carnegie Foundation has offered to make a donation of $12,000 to the association on condition that the medical profession shall raise $3,000. When this fund is in hand the association will be in a position to resume its activities which have been somewhat curtailed because of lack of funds. While the association thoroughly appreciates the gift, there is a feeling among certain members of the profession that inasmuch as they are contributing the work necessary to carry out the plans for widening the scope of medical educational facilities in New York from which the public will ultimately derive the benefit, funds should be forthcoming from sources other than the medical profession.

A Correction.—In the issue of July 9 the author of the article entitled "A Case of Epidemic Meningitis Treated by Combined Serum and Vaccine Therapy," page 67, is given as Dr. Charles E. Nammack. This is an error. The author of the article in question is Dr. Charles H. Nammack.

The Far Eastern Association of Tropical Medicine, which held its third session at Saigon, in 1913, planned at that time to hold its next meeting under the auspices of Dutch medical authorities at Batavia, in 1915. Circumstances brought about by the war necessitated the postponement of the meeting. The committee responsible for the next meeting believes that conditions are now sufficiently stabilized to warrant an attempt to revive the association, and plans have been made for holding the fourth congress in Batavia in August of this year.

Franco-Polish Medical Congress.—This congress will be held next September, jointly at Posen and Warsaw. A two-day session at the former city is to be followed by a five-day session at the metropolis.

Death of Waldeyer.—The decease of this famous

anatomist, which occurred last February, seems to have passed unnoted in most of the medical journals. He is best known to-day through his great work on the topographical anatomy of the pelvis, and through the expression "Waldeyer's ring," to denote the four tonsils and other lymphoid tissue of the throat. Originally of the Strasbourg faculty, he was called to Berlin, where he remained throughout the rest of his career.

Food Poisoning in the Government Hotels.—A number of women living in the Government Hotels on the Senate and Union Station plazas in Washington were made seriously ill recently, apparently by food poisoning. The two suspected articles, a crab-meat salad and icecream, are being analyzed by the District Health Department in the endeavor to discover the offending substance.

Yellow Fever in Peru.—According to statements published in Lima, Peru, attributed to Dr. Henry Hanson, who is in charge of the sanitation campaign directed against yellow fever by the Peruvian Government and the Rockefeller Foundation, nearly 1,000 deaths from yellow fever have occurred during the past nine months in the departments of Lambayeque and La Libertad. The Rockefeller Foundation contributed $20,000 to fight the epidemic, which is now reported to be decreasing as a result of the campaign. Owing to the work of Doctor Hanson's staff, composed of three supervising inspectors, five Peruvian physicians and 100 inspectors, it is believed that the infected districts will be entirely free from the fever by the end of the year.

Red Cross Work in China.—Advices from the National Headquarters of the Red Cross in Peking state that the work of the American Red Cross has reached such proportions that 611,000 people have been saved from starvation. The relief in many instances took the form of furnishing employment to the heads of needy families in the construction of new roads, payment being made in food. More than 74,000 men were thus employed. Conditions in China have rendered evident the necessity for the continuation of the instruction of Chinese children in simple health laws. To meet this need and to support a Chinese visiting nurse, the National Children's Fund of the Junior Red Cross has made a donation of $5,000.

Inspection Shows Ex-Soldiers Well Cared for by State.—In response to a demand for an investigation of the Manhattan State Hospital for the Insane, where it was alleged that many ex-soldiers were not receiving proper care, Governor Miller and other members of the State Board of Estimate and Control have inspected the institution. They report that they were much gratified to find that the ex-service men were extremely well cared for and that the criticisms are absolutely groundless. Governor Miller states that on the whole he has found good conditions in all the institutions which he has visited.

Dr. Lucius A. Salisbury, division surgeon for the Twenty-seventh Division, National Guard of New York, has been made colonel of the new 102d Medical Regiment. He will have control of all the medical activities of the entire State Guard.

People's Hospital Acquires Realty.—A short time ago the People's Hospital purchased the property at 222 and 224 East Fifteenth Street, New York, and recently it has acquired title to 230 East Fifteenth Street. It is understood that several other parcels will be acquired by the hospital as a site for a modern and completely equipped hospital building.

Obituary Notes.—Dr. GEORGE KNOWLES SWINBURNE of New York City died suddenly of heart disease in Rye, N. Y., on July 23, at the age of sixty-three years. He was graduated from the College of Physicians and Surgeons, New York, in 1885. He was a member of the American Medical Association, the American Association of Genitourinary Surgeons, the American Urological Society, and the New York Academy of Medicine. He was genitourinary surgeon to St. Mark's Hospital and the Good Samaritan Dispensary.

Dr. HERBERT LEE GRAY of New York, a graduate of Johns Hopkins University in 1906, died suddenly of heart disease on July 23, at the age of thirty-nine years. He was a member of the American Urological Society, genitourinary surgeon to the New York Hospital Dispensary, and chief of the genitourinary clinic of Demilt Dispensary.

Dr. LAWRENCE CONTESSA of New York, a graduate of the Long Island College Hospital in 1909, died at his home on June 21, at the age of thirty-eight years.

Dr. EDGAR M. ROSE, director of the Division of Child Hygiene of the New York State Department of Health, died of acute indigestion in Albany, on June 22, at the age of thirty-seven years.

Dr. JAMES J. MITCHELL, a retired physician of Gurdon, Ark., died on June 16, at the age of seventy-five years. He was graduated from the St. Louis College of Physicians and Surgeons in 1883.

Dr. EUGENE B. DUNBAR of Manchester, N. H., a graduate of Dartmouth Medical School in 1887, died after a long illness on June 19, at the age of sixty-two.

Dr. WALTER H. HITCHCOCK, a graduate of the College of Physicians and Surgeons, New York, in 1883, died at his home in Norwalk, Conn., June 21, at the age of sixty-four years.

Dr. EVERETT S. TOWNE of South Willard, Vt., was accidentally drowned while sailing a boat on June 18. He was graduated from the Medical Department of the University of Vermont in 1914. He was thirty-seven years of age.

Dr. LOUIS J. BECHTOLD of Belleville, Ill., a graduate of Washington University Medical School, St. Louis, in 1871, died suddenly on June 17, at the age of seventy-three years.

Dr. SAMUEL BUFFINGTON GORDON, JR., of Salinas, Cal., a graduate of New York University Medical School in 1889, died of uremia in a local hospital on June 11, at the age of fifty-three years.

Dr. WILLIAM S. GRIMES of Wapello, Ia., a graduate of Rush Medical College in 1874, and a Civil War veteran, died on June 7, at the age of eighty years.

Dr. JOHN HENRY MOON of Cooperstown, N. Y., a graduate of Albany Medical College in 1872, died of uremia in a local hospital June 28, at the age of seventy-two years.

Dr. ROSWELL R. HUBBARD of Los Angeles, a graduate of the Eclectic Medical College, Cincinnati, in 1879, died on June 10, at the age of sixty-nine years.

Correspondence.

BACTERICIDAL ACTION OF HEAT IN GONORRHEA.

To the Editor of the Medical Record:

Sir:—I have read with great interest in a recent issue of the Medical Record an extract from the *Wiener klinische Wochenschrift* of an article on the cure of gonorrhea in a woman by an intercurrent fever. In my practice within the past twenty-five years I have had occasion to observe a number of such patients passing through an attack of typhoid fever, malaria, and the like.

My first observation of the "heat-cure" of gonorrhea was in a young man who had contracted that disease and whom I had been treating for several days when he came down with typhoid fever. The only nurses he had were his mother and sister. One of them was in constant attendance and I had therefore no opportunity to treat the young man locally, so I simply had to leave the gonorrhea to take care of itself. When he recovered—in fact, long before I ceased attendance upon him for his typhoid attack—he was entirely relieved of his gonorrhea, and there were never any symptoms of it afterwards.

I subsequently had occasion to treat several patients under the like circumstances, and the results were always the same. Hence my treatment of gonorrhea, for a number of years past, has been by means of hot irrigations, and the success of the treatment has been marked. It beats all the medicinal treatment ever.

P. H. Anderson, M.D.

1404 Exchange Building,
Memphis, Tenn.

AS TO BEING OUT OF STEP.

To the Editor of the Medical Record:

Sir:—When I read the title of a letter recently contributed to your columns (July 23, 1921), by Dr. Ernest S. Bishop, my first impression was that "All out of step with Jim" referred literally to his friend, Dr. James F. Rooney, recently elected president of the Medical Society of the State of New York, as there can be no question but that Dr. Bishop knows him intimately enough to call him Jim, while Prentice's name is Alfred. The nature of the statement gave me no strong lead, as it was as applicable—and as inapplicable—to one as the other.

Dr. Bishop probably overlooked a rather important letter signed by Arthur D. Greenfield, Attorney-at-Law, in the *New York State Journal of Medicine*, July, 1921, refuting statements which appeared in "a mimeographed circular letter (which) was sent to the secretaries of all the County medical societies and the delegates to the State Society, signed by James F. Rooney, chairman, Committee on Legislation." Dr. Rooney had charged that the Fearon-Smith bill "was drawn by Mr. Greenfield, an attorney of New York City, in conference with Drs. A. Lambert, A. C. Prentice, E. Eliot Harris, and Mr. Towns, of the Towns Sanatorium for Drug Addicts, located in New York City, with certain others." Mr. Greenfield's statement says:

The impression was created by the letter as a whole, as well as by the statement quoted, that the bill was drawn in the interest of Mr. Towns and other owners of private institutions for the treatment of drug addicts. As an injustice has been done to me by the circulation of this false statement, I trust you will permit me the use of your columns to deny it. The fact is that in the planning and preparation of the bill I had no conference with any of the four gentlemen mentioned except Dr. Harris. I have never had any communication with Mr. Towns or anyone representing him, regarding this or any other bill. I have no idea what his attitude toward the bill may be. The persons with whom I consulted in the preparation of the bill were officials of the New York State and County Medical Societies, of the Federal Government, and of the New York City Health Department.

If these officials were "all out of step with Jim", it is obvious that Dr. Prentice is not "Jim" this time. There must be (and we know there is) another, real "Jim."

Dr. Bishop in his letter, gives the impression that Dr. Rooney's attitude in relation to drug addiction received endorsement by his election to the presidency of the State Society. As one who was a member of the House of Delegates and present at the meeting, I should say Dr. Rooney was elected in spite of the effect of this attitude. The convention was practically stampeded for Dr. Rooney when a certain eminent delegate gave Dr. Rooney all the credit for defeating the Chiropractic bill this year. And despite his election to the presidency, he was unable to get an endorsement of the "second Smith-Lord bill" either on the floor of the House or afterwards in the Council of the Society, to which it was committed.

In my opinion, Dr. Rooney is largely responsible for the chaotic conditions now existing in New York State, and New York City in particular, for the lack of a State law to enforce the Harrison act. The "first Smith-Lord bill", supported by practically unanimous approval, was the only drug addict bill endorsed by the House of Delegates this year and signed by Governor Miller. It abolished the New York State Bureau of Narcotic Drug Control.

Dr. Rooney has a strong personal following but it was not strong enough to get an endorsement of the "second Smith-Lord bill" which would have permitted continuance of the ambulatory (or office) treatment of addicts, and which as well as the Fearon-Smith bill was in the hands of the Governor. The latter bill prohibited ambulatory treatment and made legal provision for the care and disposition of addicts in this State. The division hinged on the question of ambulatory treatment. The Fearon-Smith bill, opposed by Rooney, approved by Prentice, was strongly advocated on the floor of the House by Dr. William P. Healey, Chairman of the Committee on Legislation of the Medical Society of the County of New York. It had been recently endorsed by a vote of the New York County society. Its main features (according to Dr. Rooney himself), were essentially the same as those of the Cotillo bill which the State Society had endorsed the previous year. Dr. Prentice has supported it consistently.

In answer, therefore to Dr. Bishop, I have called attention to some few individuals and groups who agree mainly with Dr. Prentice. Prentice has very strong convictions and has expressed them dogmatically. But *he* has not changed his step, and

is not *out* of step with everybody, and furthermore, his name is not "Jim."

J. MILTON MABBOTT, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 28, 1921.

Medical Secrets.—An interesting discussion took place recently between Mr. Justice Horridge and a medical man who was called upon to give evidence respecting venereal disease from which, it was alleged, his patient, a party to a divorce suit, had been suffering. The privilege of exemption was claimed by Dr. John Elliott of Chester, who entered the witness box. Justice Horridge said there was no privilege for a doctor in the divorce court. Witness explained that he and other medical men formed a particular clinic on the distinct understanding that professional secrecy of what happened would be observed and upheld by the Ministry of Health. The judge said that he was sorry, but the Ministry had no power affecting the jurisdiction of the divorce court. Doctors were subject to the orders of the court and had to disclose what they knew. Doctor Elliott did not wish to deny this ruling, but only desired to point out how painful it was for medical men in such cases. The judge then asked if any statute could be produced which would uphold the contention of the witnesses. Doctor Elliott referred to a regulation under the Public Health Act. The judge said, "Yes, Article 2, Sub-section 2; that may be a very good regulation between yourselves, but it has nothing to do with these courts." Witness said patients at the clinic were not referred to by name; they were only identified by a number, and the register was always kept under lock and key. The judge remarked that that did not affect the jurisdiction of the King's Courts. The doctor went on to point out that some medical men undertook the duties simply in the interests of the public. They thought it a public duty to try to abate this terrible disease, and they little anticipated that they would be placed in such a painful position as he now stood. He craved the indulgence of the court to protest at having to stand up publicly and violate one of the earliest and most sacred principles of the medical profession, one which the profession held most dear. The judge said he could not see anything painful about it. A medical man was bound to observe the regulations not to disclose voluntarily information he had obtained, but so far as regards giving information, which he was bound to give in assisting the administration of justice, it was his duty to give it. Doctor Elliott said that medical men did not undertake not to disclose voluntarily professional secrets; they undertook not to disclose them at all. It was one of the tenets of the medical profession that confidence must obtain between doctors and patients. He hoped the judge would recognize their position. The judge thought it was not an unfair obligation on doctors to assist in the administration of justice. Doctor Elliott said there was another point he would like the judge to listen to, that was the effect of not keeping these proceedings secret. The judge said he had nothing to do with that, and Doctor Elliott said he must bow to his ruling and give evidence.

It would seem that in this country the jurisdiction of the courts stands above regulations passed by departments of government, if, in the opinion of that court, such a course will assist justice. However, the last has not been heard of the matter, for while courts of law are notoriously jealous of their powers and privileges, the medical profession is no less jealous of its ethics, hallowed by tradition. Moreover, it is by no means obvious that the divulging of medical professional secrets, especially those relating to venereal diseases, will do good and this, after all, is the outstanding consideration and is of far greater consequence than upholding the powers and dignity of the courts. There are times when common sense rates higher than the law as administered by the courts, and the divulgence of medical secrets may be a case in point.

Annual Report of the Medical Officer of Health for Norwich.—The annual report of Dr. H. Cooper Pattin, the medical officer of health for Norwich has just been issued. The birth rate for 1920, 25.6 per thousand of the population, of all ages, was in advance for that of 1919, 16.35, but below the average birth rate for the 96 great towns of Great Britain—namely, 26.2 per 1,000. A satisfactory additional saving of infant life, too, as compared with 1919 took place, the infant mortality rate, 74 per 1,000 births, being 12 per 1,000 births below that for 1919; of the children born there was again a majority of males, 162; in 1919 this majority was 79; 165 of the infants born were known to be illegitimate. The mortality rate of these illegitimate infants was, as is usual, much higher than for those born in lawful wedlock. The infant mortality rate for the illegitimate being 133 per 1,000 births, the corresponding rate for the legitimate infants being 71 per 1,000 births. In other words, the chances of surviving for one year, for the illegitimate, were, roughly, about half as good as those of the legitimate. And these chances would have been lessened but for the efforts made by the health visitors and some voluntary workers.

The situation in Norwich as regards venereal diseases, according to the report, is not satisfactory. The attendance of new cases at the clinics has not increased; but so far as Doctor Pattin could perceive there has not been any decrease in disease—judging from the notifications of ophthalmia neonatorum there has been some increase. With regard to measures to abate the evil, the medical officer of health for Norwich has this to say: "To one whose training and professional bias is all in favor of prevention, the practical limitation of effort to pointing out the danger, to moral suasion, and the provision of treatment is not satisfactory. Yet to deal with this matter effectively one has to incur the possibility, and certainly the imputation, of contributing to promiscuity, and one cannot, and I certainly do not wonder that health committees, representing as they do various mental attitudes, are impelled very carefully to feel their way. I am satisfied that instruction as to danger and moral exhortations

will not materially bring about for the existing generation any satisfactory result, human nature being what it is, and the sexual remaining one of its most powerful impulses; but that instruction, plus training of the faculty of self-control from early life, will; and a man of from 20 to 30 will be able to control the sexual, because from childhood he has been trained and taught to control his selfish nonsexual impulses; in short, has learned to exercise and, by exercising, to strengthen self-control. It will be a long, uphill fight, and for the welfare of the race I am satisfied it will have to be fought. But here and now it may be said that it is the folk who have never been made to practise self-control in nonsexual impulses who naturally are incapable of controlling the sexual and are to be pitied, even while they are to be dreaded, and whose upbringers are yet more to be blamed."

New Medical School Opened at St. Thomas's Hospital.—June 21 was the anniversary of the modern St. Thomas's Hospital. It is fifty years ago that Queen Victoria opened the magnificent buildings, opposite the Houses of Parliament, which now constitute St. Thomas's Hospital, and on June 21 the Duke of Connaught, the only surviving son of the Queen, presented the medical school prizes and opened the new building of the school of physiology. This building has been found necessary in order to increase the accommodation of the school, and the structural alterations which have been carried out in the building formerly used as a students' club will give the medical staff two additional laboratories, one of which will be devoted to the teaching of chemical physiology and the other to histology and experimental work. The addition of a third floor to the wing affords accommodation for a lecture theater and the experimental and research rooms. The new school has been named after Prof. C. S. Shettington Wynflete, professor of physiology in the University of Oxford and president of the Royal Society of Medicine, a former student and teacher in St. Thomas's Hospital Medical School. The distribution of prizes preceded the opening ceremony, and Sir Arthur Stanley, treasurer of the hospital, referred with pride to the progress that had been made both in the hospital and in the medical school during the past fifty years. Alluding to the practice which obtained in some hospitals of making payments by patients compulsory, the speaker said they hoped never to have that at St. Thomas's. Their experience in the past had been that patients realized to the full the value of the treatment they received, and were always ready to give even more to the hospital than if they were applied to for a fixed sum; a fact which showed that one need not despair of the voluntary system. The Duke of Connaught, in opening the new buildings, said, in part, that there was an enormous number of hospitals and there was great competition among them, as all would wish to have, and that being so, it gave them great satisfaction to know that St. Thomas's maintained the high position which it had held for so many years. Referring to the large number of medical men who left the hospital to take their places in the forces, the Duke of Connaught said he should like to say as a soldier the great respect they had for those who worked so strenuously to promote the well-being and alleviate the suffering of those gallant men who served in the war.

Health Insurance Economy.—Sir Alfred Mond's bill (Sir Alfred is the new minister of health) to amend the financial provisions of the National Health Insurance Acts, the text of which has just been issued, is based on the recommendations of the recent Departmental Committee on Approved Societies' Administration Allowance. The bill does not make any change in the rates of contribution or normal rates of benefit under the acts, but in order to enable the administration allowance for approved societies to be increased from four shillings and five pence to four shillings and ten pence per member per annum, it proposes to make a small reduction in the amount retained out of each weekly contribution for the purposes of the Contingencies Fund, thus leaving a greater amount in the general funds of societies, out of which the administration allowance is provided. The proportion, two-ninths, of the cost of benefits and administration to be provided by the Exchequer remains unaltered. Provision is made for the contribution from the funds of approved societies toward the administration expenses of insurance committees being increased by two pence per member per annum, with a corresponding relief to the Exchequer. The net saving to the Exchequer under the bill will be about £300,000 as from January 1.

Early Portuguese Contribution to Tropical Medicine.—At a meeting of the Royal Society of Tropical Medicine, held at the rooms of the London Medical Society on June 3, a paper by Dr. Carlos Franca, Collares, Portugal, was submitted for publication in the Society's Transactions. The paper dealt with the first mention of some of the tropical diseases, ascribed to certain Portuguese physicians in the sixteenth and seventeenth centuries. The references included an account of cholera by Garcia da Orta (1583), of yellow fever by Ferreira da Rosa (1694); also descriptions by travelers who were not medical men; of scurvy by João de Barros (1522); of the cholera epidemic of 1543 by Gaspar Correia, and of *Dermatophilus penetrans*, in the production of what is now commonly known as "chiggers," by Gaspar Affonso (1596). Mention was also made of a work of the sixteenth century containing a clear account of the part played by insects in the transmission of *frambœsia tropica* (yaws), written by Gabriel de Sousa, a Portuguese colonist of Brazil, in 1587. The account given by this shrewd observer of the sixteenth century had waited for over three centuries for verification by the work of Castellani, who demonstrated experimentally in 1907 that the house fly (*Musca domestica*) could transmit the spirillum, *Treponema pertenue*, of yaws. It was, therefore, rightly claimed that the name of Gabriel de Sousa was one which should henceforth figure in the history of tropical medicine.

Obituary.—Dr. John Matthew Fortescue-Brickdale, physician to Clifton College and to the Royal Infirmary, Bristol, died in Clifton on June 2. Doctor Brickdale, in addition to the posts mentioned above, was lecturer on pharmacology at Oxford

University. He was a writer of considerable note, his writings being mainly devoted to the chemistry and therapeutic actions of drugs. Collaborating first with Professor Francis in a "Chemical Basis of Pharmacology," he brought out in 1910 a "Practical Guide to Newer Remedies" and later, with Mr. H. G. Armstrong, a book on "Infectious Diseases in Schools."

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, July 1, 1921.

Twenty-five Years of the Rontgen Rays.—A few weeks ago the Radiological Society of Switzerland held its annual meeting at Zurich. During the scientific part of the meeting several very interesting papers were read, in particular one by Professor Naegeli and another by Doctor Schinz, director of the Radiological Institute of the Cantonal Hospital of Zurich, entitled "Radiology of the Abdomen." During the dinner, which took place at Hotel Victoria, the president of the society, Dr. Hermann Suter, recalled in his speech that this year was the twenty-fifth anniversary of the discovery of the Röntgen rays and suggested that a memorial plate should be placed on the house where Röntgen lived while a student at Zurich.

Anniversary of Doctor D'Espine.—June 30, a festival was tendered to Dr. Adolph D'Espine, professor of clinical pediatry and theory and practice of medicine, to celebrate his forty-fifth anniversary as professor at the University of Geneva and as a sign of esteem upon the occasion of his withdrawal from the Faculty of Medicine, he having attained the age limit of seventy-five. The name of D'Espine is too well known to the medical profession throughout the world to require any particular account of the work he has achieved. Appointed to the professorship at the age of thirty, D'Espine was already known, especially by his "Traité des Maladies de l'Enfance," written with his friend, Dr. C. Picote of Geneva. This work has gone through some eight editions and is still a popular textbook in Europe. Throughout his well-filled life D'Espine's scientific activity has never slackened, and the number of important papers on diseases of children due to his pen or by his assistants and students would form a list too long to mention. Dean of the Faculty of Medicine from 1898 to 1900, vice-rector of the university from 1900 to 1902, rector from 1902 to 1904, it was D'Espine who organized the first *Dies Academicus*, in 1904. D'Espine is the vice-president of the International Committee of the Red Cross Society and is connected with many other philanthropic works. Among the long list of honorary presidents of the festival we would mention, as representing the English-speaking profession, Sir Archibald Garrod, Regius Professor at Oxford, who succeeded the regretted Osler, and Dr. John Lovett Morse, professor of pediatrics at Harvard University.

Cause of the Malarial Paroxysms.—Some very interesting work on the pathogenesis of malarial paroxysms has been carried out by Dr. Georges Senevet of the Pasteur Institute of Algiers, and as the results have not as yet appeared in the medical press, I will state them briefly, as they are not devoid of interest. Doctor Senevet shows that paludism has a primary phase in which the paroxysms, due to the præcox, assume the aspect of a continued-remittent fever, the result of the combined action of ordinary schizogony and binary division of the small annular forms of the parasite. Then, either from reaction of the organism or from the effects of treatment, the formation of gametes takes place, and from this time on the patient is doomed to a series of paroxysms separated by phases of apyrexia. Each paroxysm is due to segmentation of the rose bodies, which occurs early, from four to five hours before the occurrence of the paroxysm, provoking a hemoclastic crisis similar to that preceding certain attacks of asthma or urticaria. The malarial attack is similar to the reaction following an intravenous injection of heterogenous albumin. Then the reaction of the organism makes itself felt, the gametes form, the parasites which have not undergone their evolution rapidly die and this is the apyretic phase which lasts until the defensive attitude of the organism weakens. The gametes enter upon parthenogenesis; the asexual types reappear and with them arise the febrile phenomena of relapse. Periods of paroxysms and periods of apyrexia alternate with each other during the entire duration of the season of the year favorable to the parasite. When the end of the favorable season comes, the paroxysms cease and the patient appears to be completely cured, unless he harbors another malarial parasite for which this time of year is propitious, or some peculiar circumstance, such, for example, as being chilled, awakens the parasite and hence provokes some paroxysms outside of the favorable season. When the favorable season returns the following year, the patient will suffer a relapse unless he has gone to live in some country which, on account of its climate, renders the human organism unfit for the development of the parasite in question.

From these facts some therapeutic indications might be derived, but Senevet is disinclined to formulate any, as he has studied the spontaneous evolution of paludism rather than the effects of quinine treatment on the disease. He believes that any conclusion as to treatment is infinitely dangerous, and he refers to mistakes committed by some practitioners who, observing their cases at the end of the season, have taken for the effect of their treatment the more natural evolution of the diseases. Senevet's researches on the pathogenesis of malarial paroxysms show how many obscure aspects of the infection still remain to be elucidated.

LETTER FROM BELGIUM.

(From Our Own Correspondent.)

LIÈGE, July 10, 1921.

Chronic Scopolamine Poisoning.—Doctor Alexander of Brussels reported an interesting case at a recent meeting of the Société Clinique des Hôpitaux de Bruxelles. The patient was a woman, 38 years old, who had suffered for ten years past from severe menstrual pains, for the relief of which she had had recourse to hypodermic injections of large doses of scopolamine. The toxic

symptoms produced were, so far as the delirium and agitation were concerned, similar to those following the use of atropine, but the dryness of the throat characteristic of belladonna poisoning was not present.

The Belgian Neurological Society recently celebrated the seventy-fifth anniversary of its foundation. The meeting was held at the Anatomical Institute in Leopold Park, Brussels. The president, Doctor Decraene, and Doctor Crocq opened the proceeding with eulogies of the founders of the society, especially of the lamented Van Gehuchten. Drs. Alexander and R. Levy read papers on Senility, the first taking up the psychological aspect, the second discussing the subject in its anatomical relations. Dr. F. Mott of London was a guest of honor.

Ossification of Berton's Ligament.—At a recent meeting of the Belgian Surgical Society, Doctor de Caestecker of Gand reported a case of complete ossification of the iliofemoral ligament. The patient was a man who had a prevalent arthritis of the knee, following a wound by a shell fragment. After months of suppuration the inflammation subsided, leaving an ankylosed joint. It was then discovered that the hip joint was immobilized by a hard tumor, appearing under radiography to be an osteoma. It was excised by Doctor Willems and found to be an ossified iliofemoral ligament. The operation was entirely successful in restoring motion to the hip.

Paranephric Fibrosarcoma.—At the same meeting Doctor Paniel of Brussels reported the case of a patient operated upon by Doctor Huet for the removal of a paranephric fibrosarcoma. The patient had been under observation for several years, in the course of which he had had several periods of increase and diminution in the size of the tumor, accompanied by a febrile reaction. By means of cystoscopy a senile tumor was excluded. There was profound anemia. The tumor filled the left side of the abdomen, extending down into the iliac fossa and passing to the right beyond the median line. The growth was easily removed through an intraperitoneal incision, but the already greatly weakened patient died soon after the operation.

Personal.—The city of Brussels has appointed Dr. O. Gengou director general of hygiene and medicine. Doctor Gengou is professor at the University of Brussels and subdirector of the Pasteur Institute at Brabant, where he is associated with his brother-in-law, Dr. Jules Bordet. Drs. J. Bordet and Henrijean of Liège have been elected foreign associate members of the Academy of Medicine of Paris.

3. Report of a Case of Extensive Angioma of the Head, Face, and Neck, with Attacks of Fever and Somnolence.—George Blumer reports the case of a man, 49 years of age, who was born with a nevus of the forehead external to the outer angle of the right eye. At the age of five years an attempt was made to treat it with the electric needle, but nothing had been done since that time. He had had no symptoms referable to the condition until at the age of 30 years he began to have attacks of fever and somnolence progressing to unconsciousness as time went on. The angiomatous process involved both sides of the neck, the right temporal region, the ocular conjunctiva on the right side, the cheeks, the hard and soft palate, the right half of the tongue, and the pharyngeal walls as far down as could be seen. The physical examination was negative with the exception of slight enlargement of the heart and a slight systolic murmur. The eyes showed no pronounced abnormality. Lumbar puncture showed a clear fluid under pressure. The *x*-ray of the skull showed general thickening of the tables with the vascular depressions somewhat more marked than usual. There was absence of the frontal sinus, and numerous circular areas of increased density in the zone occupied by the angioma. The laboratory findings were negative except for a slightly increased blood nitrogen. A search of available literature reveals no case on record in which such extensive localized thrombosis seems to have occurred. It seems legitimate to suspect that the febrile paroxysms were dependent upon the formation of fresh thrombi in the angioma, even though blood cultures from the sinuses were negative during the febrile periods. But the extensive local thrombosis could not account for the succession of paroxysmal symptoms. The history of the case suggests socalled cirsoid aneurysm or angiomata of the pia, as the patient has at times shown definite staggering and slight nystagmus. Blumer concludes that in this case there must be an association of an external angioma of the cranium and face, with an independent internal angiomata involving the pia mater. In some very exceptional cases there is communication between the external and internal processes; there is no evidence of such connection in the case herewith reported.

4. Paresis: Treatment by Arsphenamin and Mercury.—Clarence A. Bonner has followed a series of 28 cases of general paresis treated at the Warren State Hospital, Pennsylvania, between July, 1918, and July, 1920, with a view of determining the possible benefit of combined treatment. Weekly injections of arsphenamin beginning with 0.3 grams and pushed to a maximum of 0.6 grams were given. Inunctions of mercury were given as consistently as possible, and each case received for one month potassium iodide in a dosage of 30 grains per day. The results indicate that the course of the bedridden stage is lessened by this treatment, and that dying patients do not linger so long in the usual wretched state. Serology bears no relation to remission. Duration of ward life seems to be lengthened. The results of treatment are found to be favorable, but do not warrant a change in the prognosis. Certain cases respond to the treatment while others do not. No explanation of this fact is evident, unless it be that the meningeal type, as has been reported, offers a better therapeutic opportunity.

2. Defective Diet as a Cause of Sterility: A Study Based on Feeding Experiments with Rats.—Edward Reynolds and Donald Macomber describe their experiments with rats having the standard mating fertility of 65 per cent. when on the stock diet of the laboratory. In the experiments the deficiencies chosen were those most often present in persons belonging to the well-fed classes in the United States. A diet deficient in both calcium and protein was also employed. This diet gave an approximated representation of the most important deficiencies in the war and postwar diets from which portions of Europe have been and still are suffering. These diets reduced the mating fertilities of the rats from the normal 65 per cent. to 55, 31 and 14 per cent. for low fat soluble, low calcium and low protein, respectively. The fertility of rats fed on the double deficiency diets was reduced as low as 0.06 per cent. Sections from the ovaries and testicles of such animals showed decided changes. The experiments support the belief that many infertilities are functional rather than due to anatomical or pathological causes; that very moderate degree of fertility in both individuals may produce a completely infertile mating; and that as proved in these breeding experiments, two rats that are infertile for each other may both be fertile to other individuals, not because of obscure incompatibilities, but merely because of decreased percentage of fertility in each. Cases are cited in human beings in which infertility was dependent upon dietetic deficiency and upon extreme constipation and lowered general physical condition, and which suggests that a decision that a given infertility is dependent on anatomical cause and demands operation should not lead to neglect of accessory constitutional conditions.

4. Carcinoma Developing on Gastric Ulcer.—Dr. Charles H. Mayo states that in Hunter's investigation in behalf of the New York Life Insurance Company to determine a basis for insurance following the operation of gastroenterostomy for ulcer, the results of 2,431 gastroenterostomies were studied. Of these all but 108 patients were traced, 22 of whom had had ulcers of the stomach. Of this series 521 patients with ulcer of the stomach were under observation for a period of three and six-tenths years. The mortality was 17 per cent.; the first year it was four and one-third times the death rate in a like group in the general population; the rate diminished during the remainder of the period. One thousand six hundred and fifty-one patients with duodenal ulcer were under observation for an average of three and four-tenths years; the mortality was 5 per cent., which is practically that of the normal death rate of an equal number of people in the general population of the same average age. Ninety-one persons with gastric and duodenal ulcers were under observation for an average period of three and eight-tenths years; the mortality was 15 per cent. From such statistics it would appear that there is a tendency to belittle the dangers of ulcers of the stomach. The condition occurs less frequently than duodenal ulcer but is more serious. As a rule ulcers of the stomach or duodenum are not operated on early, but only after a complaint of some years' duration. Often patients appear for a general examination because of loss of appetite, loss of weight and strength, with increase in pallor, and are found to have extensive cancer of the stomach without distress or appreciable bleeding. In 1919 and 1920 at the Mayo Clinic a diagnosis of cancer of the stomach was made in 1,529 cases. In approximately 54 per cent. the condition was considered inoperable. In 162 cases an exploratory operation only was performed. In 74 gastroenterostomy was performed for the relief of obstruction as a palliative operation. Two hundred and twenty-three patients were subjected to radical resection of the stomach. More could have been done for many of the patients had the condition been recognized earlier. It will take years of observation to estimate fairly accurately the percentage of cancers which have developed on ulcers. The exact starting point of cancer of the stomach is unknown and probably will remain unknown, but early cancers in this organ have been seen in the mucosa in the borders of chronic ulcers. From what has recently been accomplished in the treatment of cancer by the development of serum therapy, endocrine therapy, roentgen ray treatment and radium emanations, Mayo predicts the possibility of surgery becoming an adjunct to these methods instead of the major method of treatment.

5. Prophylaxis and Serum Therapy of Yellow Fever.—Hideyo Noguchi refers to his previous work and that of other investigators who have succeeded in the transmission of yellow fever from man to guinea pigs and the isolation of *Leptospira icteroides* during different epidemics. He asserts that anti-icteroides serum reduces the mortality in yellow fever when used on or before the third day of the disease. Of 170 cases, 95 were treated on or before the third day, with 13 deaths, or a mortality rate of 13.6 per cent. while the average death rate of untreated patients during these epidemics has been 56.4 per cent. On the other hand, treatment with serum after the fourth day has no appreciable effect, since there were 39 deaths among 75 patients, a mortality of 52 per cent. Prophylactic inoculation by means of the injection of 2 c.c. of the killed culture of *Leptospira icteroides* (containing at least 2,000,000,000 organisms per cubic centimeter) is of definite protective value. Among 3,230 persons vaccinated twice, no case of yellow fever developed, while 278 cases developed among the nonvaccinated, notwithstanding the fact that both groups were equally exposed to infection. The protection resulting from vaccination does not become effective until about ten days after the last injection, as shown by the frequent case incidence occurring among the vaccinated population within from one to ten days after they were vaccinated. There were 23 such cases among 7,537 persons who were vaccinated with standard vaccine.

1. Intrinsic Cancer of the Larynx: Usual Site of Origin, as Demonstrated at 50 Laryngo-Fissures, and Its Influence on Diagnosis, Prognosis, and Treatment.—St. Clair Thomson concludes as follows: 1. Intrinsic cancer of the larynx originates on the vocal cords or in the subglottic area. 2. It has never been found in the posterior commissure (interarytenoid region), nor originating from the ventricular bands or the ventricle of Morgagni in the 50 cases examined both indirectly with the mirror and by direct inspection after splitting the larynx. 3. A malignant growth may originate on any part of a cord, but is more common in the central portion or anterior half than in the posterior area of the larynx. 4. As is now well known an epithelioma originating in this region remains for a long time limited to the cord affected and the adjoining side of the larynx, but it may cross the anterior commissure, and, in later stages, it invades the arytenoid and the area to the outer side of it. 5. The inner surface of the cord may be affected primarily or by extension. The subglottic area may be invaded by a growth originating in the cord. But a cancer may also start below the level of the cords, in the subglottic area. 6. A subglottic cancer is much more common in the anterior than in the posterior half of the larynx. As regards prognosis Sir Thomson concludes: 1. That superficial and projecting tumors of limited extent are the most favorable. 2. That those situated in the middle third or anterior half of the cord are more promising than those invading the

anterior commissure in front or the arytenoid region behind. 3. That growths imbedded in a cord, or extending into it below an intact mucosa are not so favorable. 4. That an epithelioma extending along the inner margin of a cord is still less favorable. 5. Subglottic cancers are very unpromising as regards lasting cure by laryngo-fissure. They are frequently associated with impaired mobility or complete fixation of the cord. As regards operation, in every case, however limited in growth, the entire cord should be excised from the anterior commissure up to and including the vocal process of the arytenoid. The excision should go down to the lower edge of the subglottic area; above it should pass through the healthy ventricular band; and externally it must include the perichrondrium lining the thyroid ala. To facilitate this the thyroid ala should be removed so that a laryngo-fissure is really a partial hemilaryngectomy.

Hematuria as Seen by the Surgeon.—Andrew Fullerton asserts that while the general rules laid down by clinicians to enable the practitioner to make a shrewd guess as to the cause and origin of hematuria are useful, they cannot always be relied upon for accurate diagnosis. It is well to proceed as far as possible along the ordinary lines before resorting to the cystoscope or urethroscope to complete the diagnosis. An analysis of the writer's 600 cases of renal hematuria shows that 292 were due to kidney conditions, of which tubercle of the kidney furnished nearly one-third; 10 were due to ureteral calculus or injury to the ureter; 229 were due to bladder conditions, 113 of these being due to cystitis; 53 were due to enlarged prostate (including malignant disease), prostatic abscess and prostatitis; two were due to papillomata of the urethra and two to calculus in the urethra. In the treatment of hematuria of any severity the patient should be kept in bed, and morphine, if not contraindicated, should be administered. Calcium chloride or lactate, preparations of ergot and hazeline, and sterilized horse serum may be tried, or inhalations of carbon dioxide as recommended by Wright. The bleeding in cystitis should be dealt with by urinary antiseptics and lavage of the bladder. In essential renal hematuria, section of the kidney, decapsulation, fixation of a movable kidney, incision into the pelvis, with direct attack on the papillæ, etc., and injection of silver nitrate solution or adrenaline, are among the methods used. To control hemorrhage of the bladder pending more radical measures adrenaline may be used. A slower but more lasting method is irrigation with silver nitrate. In certain cases with massive clotting, an evacuating catheter similar to that used for lithopaxy may be used to remove the clots. It may even be necessary to perform cystotomy to clear out the clots. Packing the bladder is an unsatisfactory proceeding. If resorted to a way of escape must be provided for the urine, and the ureteral orifices must not be blocked. Raising the foot of the bed is helpful in some cases. No patient ought to be allowed to die of hemorrhage without an attempt being made to restore him by transfusion of blood or intravenous injection of gum saline solution.

8. A Theory of the Origin of Bacteria. Duke Mulloy.

2. The Medical Aspects of Flat-Foot.—Robert Hutchison holds that there is perhaps no common condition the symptoms of which are oftener misinterpreted than flat-foot. Flat-foot presents itself in childhood, when it is the result of laxity of muscles and ligaments, and produces difficulty in walking and deformities, but no pain; in early adult life, when it often develops quite acutely, and may cause great pain; and about middle age, when it comes on gradually as the result partly of diminished elasticity which advancing years bring, and partly in consequence of the increased strain thrown upon the arch by the rise in body weight, which so often supervenes at this time. It is these middle-aged cases which are most apt to be overlooked. The pain associated with flat-foot in these cases may be attributed to gout, rheumatism, neuritis, the lightning pains of tabes, or even to "neurasthenia." The edema of the feet and ankles which flat-foot may cause is sometimes mistaken for cardiac dropsy, and pain in the right knee and hip which result from it may be regarded as due to sacroiliac disease. It is important to remember the possibility of such mistakes. If the true cause of the symptoms is recognized, treatment is as simple as it is satisfactory. All that is necessary is to order a suitable pair of instep supports.

4. The Hero Doctor. Homer Dupuy.
5. Annual Oration—Louisiana State Medical Society. J. Zach Spearing.

2. Corrective Rhinoplasty, with Presentation of Case.—A. I. Weil describes the operation employed in the typical case reported. Modifications for other types of deformities may be made according to circumstances, whether it be for the reduction of an oversized nose, a rib or other bone implant to correct a sunken or saddle nose, and the like. The local reaction from these operations is sometimes very great, the discoloration being very marked and the swelling of the soft parts and lower lids being sometimes so great as to close the eyes. In the case cited the local reaction was comparatively slight and passed off in about a week or ten days. There was no general reaction, no rise of temperature, and no vestige of infection. A surprising feature was the almost entire absence of pain after operation, where one would naturally expect considerable pain to follow this rather strenuous manifestation.

2. The Microscopic Appearance of Two Testes Nine Months Following Unilateral Vasectomy. Homer Wheelon.
3. The Internal Secretion of Sandstroem's Glands. Parathyroid Hypofunction and Eclampsia. Aldo C. Massaglia.
4. Hypopituitarism—Froelich Type. In an Infant, Nine Months Old. M. Boyd Kay.

3. The Internal Secretion of Sandstroem's Glands. Parathyroid Hypofunction and Eclampsia.—Aldo C. Massaglia has conducted experiments which show conclusively that the thyroid and the parathyroid glands have different functions. The former exerts a trophic action on the metabolic changes of the body; when this function is abolished myxedema follows. The latter exercise an antitoxic action; when this is abolished fatal tetany is the result. Vassale and Massaglia continued the study of the function of the parathyroids, and were able to demonstrate that this tissue neutralizes the toxins arising from pregnancy and muscular fatigue. This study gave rise to the hypothesis that a hypofunction of the parathyroids can produce eclampsia. Massaglia and Sparapani found, moreover, that the eclampsia of animals is similar to the experimental tetany which occurs in the female dog during pregnancy, when there is a parathyroid hypofunction. Since the problem had not been completely solved, further studies were made, which are recounted in the present communication. It was found that the parathyroid glands appear to have the function of neutralizing or of breaking down into waste products of simpler chemical composition the complex bodies of catabolic changes, or toxic substances derived from pregnancy and puerperium, from the intestine, and from muscular fatigue. An intoxication from a parathyroid hypofunction injures, more or less, the kidneys, the liver, and the nervous system. There exists between the liver and the parathyroids an indirect functional correlation in neutralizing toxic substances which arise from the intestine. A parathyroid hypofunction in pregnancy or in puerperium is then certainly a pathogenic factor of eclampsia. This factor does not

exclude other factors in the pathogenesis of eclampsia. The explanation of the pathogenesis of eclampsia and its different syndromes is discussed. It is necessary, after the diagnosis of eclampsia is made, to discover what organ has yielded first in its antitoxic function, and so to determine the nature of the poisons causing the intoxication. Then it is possible to obtain good results by instituting an immediate antitoxic treatment with special reference to the organs first affected. This etiologic diagnosis is not easy to establish, especially when the attack occurs almost without warning. But eclampsia is most often caused by a parathyroid hypofunction, and, for this reason it is wise always to use the opotherapic treatment (parathyroidin). Moreover, this treatment should be instituted before the appearance of any strong convulsive symptoms, because when the nervous system is severely injured it recovers with great difficulty. When medical treatment is without effect, it is the part of the obstetrician to determine when it is time for emptying the uterus.

3. Remarks on the Primary Treatment of Accidental Wounds in Relation to the General Practitioner. J. A. Manzella.

3. Remarks on the Primary Treatment of Accidental Wounds in Relation to the General Practitioner.—J. A. Manzella concludes the discussion of this subject with the following surgical "don'ts": (1) Don't as a rule probe wounds. (2) Don't neglect to shave hair around a wound. (3) Don't use strips of dry gauze in corner of a closed wound, particularly a small wound for drainage; it usually makes an excellent cork. (4) Don't suture wounds tightly. (5) Don't use collodion as a primary dressing. (6) Don't be in a hurry to amputate badly crushed fingers and toes; with patience they often do surprisingly well. (7) Don't put on tight dressings or splints over wounds, particularly within first twenty-four hours; subsequent swelling and edema cause much damage. (8) Sterile adhesive strips may be used at times to coapt skin in parts not so movable. (9) Paraffined gauze strips make excellent drains. (10) Don't use catgut in skin if possible. (11) When in doubt as to the vitality of deep tissues don't close up wound entirely. (12) Don't overlook severed tendons.

Pneumonia in a Subject with Laryngeal Fistula.—Pallasse describes the case of a boy of 13 who at the age of 10 years had been tracheotomized for laryngeal diphtheria. He had worn the tube for nine months, and afterward no attempt had been made to close the fistula. When ordinary lobar pneumonia developed with its attendant dyspnea a question of scientific interest was the amount of air which passed in and out of the fistula. The pneumonia ran a mild course, defervescence occurring by the fourth day. The fistula and the natural passages were alternately closed in order to study the respiration through each of the orifices unassisted. Incidentally the part played by the larynx in the genesis of respiratory sounds was studied. In the patient in question the persistence of the fistula was due to the advice of the physicians because the calibre of the larynx had undergone some retraction as a result of the diphtheria. The intratracheal pressure of the child is ordinarily about 4 to 6 cm. water, while in speaking this is increased to 16 cm., and in crying out to 100 cm. In regard to the speed of the air which traverses the trachea it is 24 cm. per second in quiet breathing, 50 cm. in conversation and 123 cm. in crying out. These figures were obtained by Chanon and Sargnon in experiments on children in 1906. The quest of the author was limited largely to duplicating some work of Chauveau and Bondeau in pneumonia in tracheotomized horses. The only conclusion reached was that the *souffle tubaire* was not essentially modified by any of the variations in the mode of breathing.

April 30, 1921, xlix, 18

Cancer of the Tongue.—Professor Delbet gave a clinical lecture on this subject, in which he presented a patient with a large mass on one side of the tongue, despite which localization speech was possible, which fact, said the lecturer, implies that the lesion has not yet seriously involved the floor of the mouth. The buccal mucosa is the seat of leukoplakia, which indicates a defective evolution of the epithelium through which it assumes the features of epidermis. In addition the epithelium is macerated like the epidermis of a laundress' fingers. The patient gives a positive Wassermann. Epithelioma of the tongue most commonly develops on leukoplakia, either through the latter becoming papillomatous or in sequence to the formation of fissures. The relations between leukoplakia and syphilis are uncertain, but the former should awaken suspicion of the latter. When a lesion appears on the tongue one can usually exclude tuberculosis because of its rarity and of the association of pulmonary phthisis, but differentiation between epithelioma and syphilis is important from the clinical viewpoint. The association between cancer of the tongue and constitutional syphilis is known to be a frequent one, and the seroreaction will not necessarily clear up the subject. The treatment test is proper to institute but the patient cannot afford to wait idly in the interim. A biopsy must be practised at once. If the result is positive we should make a diagnosis at the same time of the radiosensibility. The basocellular epithelioma is tremendously radiosensible while the spinocellular growth is radioresistant and may be aggravated by both radium and *x*-rays. Here at the present time the knife seems indicated, although the future may find a way to neutralize this radioresistance. The author advises against radiation after surgical removal.

Kola Addiction.—Starobinsky describes a case of this malady in a woman of 57, whose mother took the drug steadily for 25 years and died at the age of 73, three days after breaking off the habit. The patient herself has been taking kola steadily for 15 years and could not work without it. She took a teaspoonful of the powdered kola every morning, and ate but little food. The author had her stop the habit, and at the end of eight days she was so weak that she took to her bed. With the kola suppressed, her behavior resembled that seen upon withdrawing morphine from an addict, so far at least as many symptoms were concerned—motor agitation, absolute insomnia, etc. Later there were mental confusion and delirium. She recovered very slowly and did not return to the drug. During the withdrawal she received only camphor as a cardiac tonic. Technically the case was one of caffeinism and the symptoms were those described by Roch under chronic caffeine addiction or intoxication. The condition is not a serious one when compared with morphinism or cocainism. The author classes it with nicotinism as a "benign addiction." The chief menace is in the lowered nutrition and the permanent hypertension. The death of the mother after sudden withdrawal was due to cerebral hemorrhage, and perhaps was only a coincidence; at any rate, suppression of the drug should have lowered and not increased the intracranial blood pressure.

Le Presse Médicale.

May 4, 1921, xxix, 36

The Neckless Subject (Klippel-Feil Syndrome).—Dubreuil-Chambardel states that the Klippel-Feil syndrome was first described in 1912 in the *Nouvelle Iconographie de la Saltpêtrière*. The original patient, a man of 47, appeared to be without a neck. The case was studied by radiography and at autopsy. In life the head seemed to be fixed squarely on the trunk, but dissection showed that all of the seven cervical with the first four dorsal vertebræ were fused into a single mass, the length or height of which was 8 cm. and the width 5.6 cm. The four upper ribs were inserted into

this mass and at the same time occupied the cervical region. The second case was reported in 1913 by Lesbre of Lyon, the third by the American orthopedist Meisen; an entire series of six by Bertolotti; the tenth by Lortet and Dupont, eleventh by Lance, and the twelfth by the present author. The latter proceeds to analyze these twelve cases after the statement that fusion of the cervical vertebræ was seen in autopsy cases long before the time of Klippel and Feil's report which first called attention to the clinical condition. Little is yet known of the etiology. Nine of the twelve patients were males and no heredity has yet appeared in the histories. Life is not necessarily shortened (Rokitansky found the condition at autopsy on a man of 70). The three clinical peculiarities which stand out are absence of neck, limitation of mobility of head and low implantation of the hair to which Feil has added a certain degree of kyphosis or round back. Conditions which might be confused with it include suboccipital Pott's, which, however, is an acquired and painful affection. The radiogram removes any doubt. Torticollis should readily be excluded, as should cervical spina bifida.

La Presse Médicale.

June 11, 1921, xxix, 47.

Myoclonic Uremia.—Roger and Chaix consider this affection as one which may simulate myoclonic encephalitis. The latter has been abundantly described of recent years and has an algic or painful component, as well as a tendency to affect local muscle groups—hiccough and nystagmus may be mentioned as examples. In this connection continuous study of uremic cases shows that similar motor phenomena may appear. The authors describe in full a case of uremia in which choreo-myoclonic movements were very much in evidence. This recalls the fact that in epidemic encephalitis there is often nitrogen retention which is usually temporary, although notes are given of a case of encephalitis which developed in a patient with an old renal lesion. This was a case of masked uremia and is instructive to the extent that in an epidemic of encephalitis, uremic intoxication might well be overlooked. Dieulafoy distinguished clinically between certain pathological affections in respect to lack of muscle control. Thus he described a slow type of uremia in which, just as the subject fell asleep, he experienced an entire series of motor phenomena—electric shocks, subsultus tendinum, twitches and the like. The subject is apt to show apathy, somnolence and hebetude, and in theory at least these local motor manifestations may pass into epileptiform seizures. Occasional variations are tetanoid or tonic spasms and jacksonian epilepsy. The condition in question is best illustrated by a case. A man of 47 complained of dyspnea, prostration, anorexia and nausea, headache, vertigo and nosebleed. The history was negative save that a year before there had been a similar experience. Upon examination there were noted certain myoclonі of the left arm, shoulder and fingers with similar behavior in the corresponding lower extremity. No prognostic significance was attached to these cloni, as the patient was quiescent a year later.

Gazette des Hôpitaux.

May 24-26, 1921, xciv, 41.

Uremia and Internal Secretions.—Rémond and Minvielle continue their investigations along this line with special reference to the antagonism of the parathyroid medication. It had been learned that ablation of these organs, which has long been accused of causing or increasing spasmophilia, can also aggravate uremia. The latter is produced by ablation of the kidneys and thyroid, and if the parathyroids are also removed the uremic state is notably aggravated. According to the endocrine theory there is a superactivity of the adrenals in uremia. The present article is devoted to the clinical aspect. The antagonism of the thyroid and parathyroids is well shown in human uremia, since the former when administered as a remedy is known to aggravate the condition, whereas, as already stated, the parathyroids act beneficially. In some of the cases cited there are no measurements of blood urea, the Ambard coefficient being used as a measure of nitrogen retention. Under parathyroid medication, including hypodermic use, the constant was notably increased. In another series of cases the blood urea was actually measured and was found to be lowered by the same drug. To cite one of the most instructive cases, a woman of 52 had had chronic nephritis for 15 years and had numerous petty symptoms of uremia along with edema and enlarged heart. There was a positive Wassermann. Blood pressure 251. Total blood nitrogen 3.14 gms., total blood urea 1.62 gms. Oliguria—but 300 ccm. urine daily. The patient had been receiving mercurial inunctions and milk regimen without benefit. When at her worst with uriniferous breath and anuria she was bled 500 ccm. and given parathyroid. Improvement was rapid in all directions, including notable fall of urinary nitrogen.

Finska Läkaresällskapets Handlingar.

March-April, 1921, lxiii, 3-4.

Visual Disturbances Caused by Wood Alcohol.—Rostedt states that since 1917 there has been a rapid increase in the number of cases of wood alcohol poisoning in Finland. The cause of this increase is clearly the attempt which began at that period to make the country bone dry. Grain alcohol has been replaced industrially by denatured spirits which contain from 2 to 3 per cent. of crude wood alcohol. The number of victims to date is 60, of whom half have been blinded. The amount of spirits actually ingested is difficult to determine, and but 8 patients of the 60 could give exact information on this point. The amount of denatured spirits drunk varied from 100 to 400 gms., which represented from 2.5 to 10 c.c. of methyl alcohol. Usually the dose taken was set down as about half a pint, which would represent 7.5 c.c., and this may be taken as the amount sufficient to blind. In most cases the visual disturbances appeared in the course of the third day of the intoxication. The course of these disturbances is very rapid and in from one to three days the acute stage is over. Following, there may be slight improvement, which, however, is not permanent. The peripheral portion of the visual field is seldom altered at the outset. There is a central scotoma which varies in size and degree. With the ensuing atrophy of the optic nerve the visual field contracts concentrically from the periphery and there are disturbances of color vision. The eyegrounds appear normal at first, but in the course of several weeks the papilla is quite paled out and may be excavated or have a greenish tinge. A highly important discovery by Hammarsten and Lindberger is to the effect that wood alcohol poisoning chiefly has to do with the crude wood naphtha, which contains toxic impurities mostly unidentified, and which comprise fusel oil. The author would therefore substitute some other form for wood alcohol poisoning. In home distilled brandy there are the same unknown or partly known impurities as occur in crude wood spirit. According to the author we know next to nothing of the toxic effects of pure methyl alcohol. It was once used in medicine and may still be found in old materia medicas with dosage of 15 to 45 minims.

Fatal Luminal Poisoning.—Chavigny and Ruhlmann relate the case of a man who in addition to a psychosis was an alcohol addict. He took 6 grams of luminal in the course of a few days and died in coma. The autopsy gave entirely negative results, as it does also in the case of animals poisoned with this drug. It is therefore difficult to prove that death was due to the drug, although morally there can be no doubt of this. —*La Presse Médicale.*

The Choroid Plexus in Endocrine Syndromes.—Sabrazès and Duperié state that there is an intimate relationship between thyro-ovarian endocrine disease and anomalies of the choroid plexus. In a case cited of thyro-ovarian insufficiency there were superadded hydrocephalus and hyperthermia, and this according to the authors spoke for a sclerogenous process in the choroid plexus. Monakow has previously asserted that the choroid plexus may participate in endocrine syndromes.—*La Press Médicale.*

Book Reviews.

CANCER AND ITS NON-SURGICAL TREATMENT. By L. DUNCAN BULKLEY, A.M., M.D., Senior Physician to the New York Skin and Cancer Hospital; Member of the American Association for Cancer Research. Price, $6.00. New York: William Wood and Company, 1921.

THIS is a well conceived book on a most important subject that should be of vital interest to every practitioner of medicine, whether internist, surgeon, or specialist. Cancer has been studied intensively for years and it is today almost as much of a riddle as it was a half century ago. Mice and monkeys, dogs and fishes have been inoculated and experimented upon in every possible way and volumes of reports of the work done have been issued, yet the profession in general is as far as ever from the knowledge that will be of practical use to cancer sufferers. It seems odd that it has never occurred to the experimenters that the proper study of mankind is not mouse but man. Dr. Bulkley is one of the few (among whom Bell of London deserves special mention) who have studied the disease as it occurs in man in all its aspects—etiology, pathology, biochemistry, and metabolism, and those who are not satisfied with what they have learned from animal experiments would do well, before settling back with a confession of invincible ignorance, to see what has been discovered by a study of the patient and his mode of life. This is already so much that one wonders whether the problem would not have been fully solved by this time had it been approached by all experimenters in the right way.

The most interesting and suggestive section of the book is the one on treatment. It should be read without prejudice, and if so read it cannot but give food for thought. It is curious that even those who believe in nothing but surgery should not be willing, after surgery has removed the neoplasm, to try medical measures just as an experiment to see whether they may not prevent a relapse. Then, if in ten years statistics show that the number of permanent cases is much greater than in former days, some credit will perhaps be given to the medical management as well as to the assumed improvement in operative technique. If any broad-minded surgeon is willing to try the experiment he will find out what to do from this interestingly written book.

PRÉCIS DE MICROBIOLOGIE CLINIQUE. Par FERNAND BEZANÇON, Professeur de bactériologie à la Faculté de Médecine de Paris, Médecin de l'hôpital Boucicaut, Membre de l'Académie de Médecine. Avec 200 figures dans le texte et 7 planches. Troisième édition entièrement refondue. Paris: Masson et Cie., 1920.

BEZANÇON'S book stands in the same relation to French laboratory workers that Hiss and Zinsser's "Textbook of Bacteriology" bears to American bacteriologists. It discusses first certain general considerations and technique, and then classifies the bacteria morphologically and considers for each organism its history, its morphology, its cultural characteristics, certain features of its biochemical manifestations, its serological behavior, and such applied serotherapeutic values as, in the opinion of the author, seem well established.

This new edition contains a chapter on anaerobic bacilli, studies of which were especially developed during the war, and for the most part by American investigators. The volume ends with a section devoted to established methods for the routine bacteriological examination of clinical material, such as blood, exudates, cerebrospinal fluid, urine, feces, buccal secretion, sputum and pus. The sanitary bacteriological examination of water and air is added to complete the value of the text in the service of health officers.

TREATISE ON GENERAL AND INDUSTRIAL ORGANIC CHEMISTRY. By DR. ETTORE MOLINARI, Professor of Industrial Chemistry at the Royal Milan Polytechnic and at the Luigi Bocconi Commercial University. Translated from the third enlarged and revised Italian edition by THOMAS H. POPE, B.Sc., A.C.G.I., F.I.C. Part 1, with 254 illustrations. Philadelphia: P. Blakiston's Son and Co., 1921.

THIS volume, which is only part of a large work, fills a unique place among works on chemistry. It deals with the subject from the theoretical side, from the practical side, and it also seeks to show the relation of chemistry to several industries and commercial pursuits. The work is on the same general plan as the author's book on Inorganic Chemistry. The present volume is divided into two parts, the first deals with some of the questions arising in connection with organic chemistry in general; the second treats of the derivatives of methane, and discusses the hydrocarbons (saturated and unsaturated), the halogen derivatives, the alcohols, the derivatives of the alcohols (aldehydes, ketones, ethers), the acids and their derivatives. The author has inserted numerous tables showing costs, and quantities, and various other statistical data. The descriptions and discussions are concise and easily understood; at the same time the author avoids excess of detail, and selects only methods which have proved their value. The book is different from any work dealing with medical chemistry, but it contains a great deal of information which will round out a physician's view of chemistry and perhaps it may lead him to take an interest in a subject which is too often neglected. The volume (with the previous one on Inorganic Chemistry) is a standard work of reference, and should be in every scientific library.

DISEASES OF THE NOSE AND THROAT. By HERBERT TILLEY, B.S., F.R.C.S., Surgeon Eye and Ear Department, University College Hospital, London; Surgeon Ear and Throat Department, King George's Hospital (Red Cross); Teacher of Laryngology and Otology, University of London; Laryngologist to the Radium Institute, London; ex-President Section of Laryngology, Royal Society of Medicine, London; Formerly Surgeon to the Throat Hospital, Golden Square. Fourth Edition. Price, $7.50. New York: Paul B. Hoeber, 1920.

THOSE familiar with the earlier editions of the work will be glad to know that this latest edition is now published in this country. The book has long been favorably known in England, and deservedly so, for it is one of the best treatises on the nose and throat now obtainable. The author is one of the leading laryngologists (or, in the time-saving jargon of the specialties, triologists) in Great Britain, and his career as a teacher has given him the ability to impart knowledge to others in clear and simple language. The book is exceedingly practical, especially in the section on treatment, the reader being told just what to do and how to do it in the easiest and most effective way.

The subject matter is arranged in the usual way according to location—nose, accessory sinuses, pharynx, and larynx. The illustrations are numerous, 266 in all, and those portraying the anatomical relation and picturing operative measures are capital, most of the latter being on plates. By this means the use of uncalendered paper for the text is made possible, and the reader is spared much eye-ache and blurring of vision. The book will be found most satisfactory by the general practitioner living in the country, and not himself an expert laryngologist yet often forced by the duties of his position to treat affections of the nose and throat and the accessory sinuses.

LABORATORY MANUAL FOR THE DETECTION OF POISONS AND POWERFUL DRUGS. By Dr. WILHELM AUTENRIETH, Professor in the University of Freiburg i. B. Authorized Translation. By WILLIAM H. WARREN, Ph.D. Fifth American Edition. Philadelphia: P. Blakiston's Son & Co., 1921.

LIKE the fourth American edition, the present edition is a translation of the fourth German edition, for a fifth German edition has not appeared. There are but few changes. Tests for methyl alcohol have been introduced and certain minor corrections made, but the book is essentially like the preceding edition. The work is familiar to many laboratory workers and has proven itself. Poisons are divided into four groups: those volatile with steam, organic substances not volatile with steam, metallic poisons, and substances not included in the first three groups. There are three chapters on special examinations and quantitative methods. It is fairly complete, although some of the more recent methods have not been introduced. Gettler's work with methyl alcohol, for instance, is not represented. It is a valuable book for those engaged in this particular line of work.

THE BASIS OF PSYCHIATRY. (Psychobiological Medicine.) By ALBERT C. BUCKLEY, M.D., Medical Superintendent of Friends' Hospital, Frankfort; Associate Professor of Psychiatry, Graduate School of Medicine, University of Pennsylvania; Alienist to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases. 79 Illustrations. Price, $7.00. Philadelphia and London: J. B. Lippincott Company, 1921.

As most medical books do, this one tells in its title its chief reason for existence. Almost 450 pages are filled with good working material for the student, provided he does not demand too detailed knowledge from the author. It begins with biological phenomena, carries through cerebral, then autonomic development, mental growth, psychological processes, etiological factors in mental disorders, different types of mental diseases, logically following through to the disorders of the senile period. It would seem rather discouraging to a student to pick up a book of this description and to find after all the newer theories tried out and proved at least worth something and worth knowing, that constitutional tendency is such a big peg upon which so many causes of mental diseases are hung. One sometimes wonders how one-half of the working world manages to earn a living, considering the amount of constitutional tendency there is abroad in the land. The author works out his chain of symptoms of the different diseases in a clear and interesting manner, but when it comes to the treatments he gives the impression of having tied himself in hard knots to the apron strings of older authorities. For instance, in the treatment of neurasthenia, and we use this because it is one of the more common conditions than the others described, he states in part, "In states of marked exhaustion very careful attention must be given to the matters of food and elimination. The amount of food should be limited to the patient's ability to digest. . . . As soon as possible eggs should be added to the milk diet." Then follows a description of how eggs should be given. Now, while great stress in this particular treatment is laid upon elimination, so far as one could find there is not any reference made to food idiosyncrasies in diet. The above treatment might completely upset many a neurasthenic patient who could not digest eggs in any form. Ideas of the relation of anaphylaxis and feeding receive scant consideration. Psychoanalysis, be it good, bad or indifferent, is coldly discussed, or rather stated over several pages, while farther on in the book, under the Psychoneuroses the author says, "The experience of the writer is in accord with that of Dercum and Lloyd that the instances in which sexual matters form the basis of worries, fears, and depressions are not in the majority; that the results to be obtained can be reached without resorting to the operation of 'mental catharsis,' which has the disadvantage of being tedious, painful to the patient, and in the end indefinite as to the accuracy of the results obtained, for the reason that it is difficult to separate clearly that which is primarily the product of the patient's mind from those psychoanalytic results which are products of the examiner's mind."

As a guide purely and simply this book is well worth possessing. It is exceedingly well written and offers fascinating reading and matter for study. In fact, the author's power to interest makes one wish that he had not attempted to cover so much ground in his specialty, but that he could have given more of his attention to the detailed development of psychiatric conditions. In fact, the author's own power to hold interest through his ability of presentation and his evident deep knowledge of his work makes the reader disappointed when he has suddenly thrust before him as he reads a collection of opinions of other authorities. The glimpses the author allows of his own deep knowledge of psychiatric states arouse a hope that at some future time he will again present this book on psychiatry, but containing not so modest an estimate of personal point of view.

THE TECHNIQUE OF PSYCHOANALYSIS. By SMITH ELY JELLIFFE, M.D., PH.D. Second, Revised and Enlarged Edition. Price, $2.50. New York and Washington: Nervous and Mental Disease Publishing Company, 1920.

IN writing of the attitude of the laity, ignorant of the tenets of psychoanalysis, the author says, "The would-be critic is usually in the position of one who, unable to decipher his own Chinese laundry check, immediately feels competent to discuss the whole subject of Oriental languages, history, and culture." Thus, you see on page 35 of this monograph, a resistance has been set up by the author, which would immediately antagonize any student of this subject unless he were sufficiently well instructed to be an analyst, then he would not need the interestingly written knowledge offered here.

Apparently, psychoanalysis is a sealed subject unless one happens to agree with the author. Nevertheless there comes drifting through the mind a wonder if, in a given case of psychoanalysis, the analyst should *not* be "large and stout—5 ft. 10 in., 200 pounds, clean shaven, with a roundish face (description of himself by author, page 85), could the unconscious, temporary love transference from patient to analyst, which seems to be a necessary process for the benefit of the analyzed, be so easily accomplished as this author quite unconsciously infers? Suppose the analyst were dark, small, thin, ugly, and severe, what would happen to the process of transference of affection from unknown depths in the patient to the person of the analyst? Apparently, either all psychoanalysts are good looking or else a wooden image and a dictograph would do as well to help carry wandering love in the patient to a safe and sane harbor, after having been measured by the psychoanalytic yard-stick of the Œdipus-complex.

Queer, too, that so many psychoanalysts are fretted with "word-complex." If the majority of them would but clothe their ideas in simple, understandable English, then perhaps the criticism made by the author of this monograph and quoted above, would not be necessary.

PRINCIPLES OF HYGIENE: A Practical Manual for Students, Physicians, and Health Officers. By D. H. BERGEY, A.M., M.D., Dr. P.H., Assistant Professor of Hygiene and Bacteriology, University of Pennsylvania. Seventh Edition, Thoroughly Revised. Price, $5.50. Philadelphia and London: W. B. Saunders Company, 1921.

ANY book the editions of which have reached the mystic number of seven has proved itself. It is nearly twenty years since this work first appeared and with each successive edition its worth has been more and more appreciated. Its popularity may be attributed to several causes, such as convenient size, moderate price, and clear and legible type, but especially to the author's handling of his subject—the judicious selection and arrangement of subjects and the very precise and authoritative descriptions given. Dr. Bergey knows his subject and he makes it easy for the reader to share his knowledge.

TRAUMATIC SURGERY. By JOHN J. MOORHEAD, B. S., M.D., F.A.C.S. Late Lt.-Colonel, Medical Corps, American Expeditionary Forces; Professor of Surgery and Director, Department of Traumatic Surgery, New York Post Graduate Medical School and Hospital; Visiting Surgeon to Harlem Hospital; Attending Surgeon, Park Hospital; Consulting Surgeon, All Souls' Hospital, Morristown, N. J.; Lt.-Colonel, Medical Reserve Corps, U. S. Army. Second edition, Entirely Reset. Price, $9.00. Philadelphia and London: W. B. Saunders Company, 1921.

THE first edition of this book was greeted warmly as one of merit and a valuable addition to the working library of the young surgeon. Other books have been written on fractures and dislocations, but the scope of this is wider, taking in injuries of all kinds, not only of the bones and joints, but of the viscera and of the external soft parts and skin, and dealing also with the results of injuries, such as shock, neuroses, etc. This second edition is enriched by the author's experience with war surgery, much of which he finds applicable to the treatment of injuries in civil life. Application is made of débridement, Carrel-Dakin irrigations, the Blake-Keller splints, Willem's mobilization treatment of joint wounds, etc.

The proof-reading of this edition seems to have been better than that of the first, for one encounters few typographical errors. The misstatement regarding the presence of crepitus and abnormal motility in impacted fractures of the surgical neck of the humerus, to which we called attention in the former reviews is repeated here on page 344.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 19, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged in cooperation with the Section of Laryngology and Rhinology.

Analysis of the Systemic and Local Conditions Following Tonsillectomy and Adenoidotomy.—Dr. CORNELIUS C. COAKLEY and EDWARD L. PRATT made this presentation, the first portion of which was given by Dr. Coakley, who stated that their purpose was to analyze the conditions found in their private patients on whom they had operated during the period from January, 1908, to July 1, 1920. He first considered the technique employed and discussed the immediate effects and complications, and then the conditions later found, as shown by the replies to a "questionnaire" sent to each patient asking for certain information, the object being to obtain each patient's view of the value of the operative procedure. In all cases in which the result was not satisfactory, a letter was sent asking the patient to return for examination, so that they might determine whether an unfavorable result were attributable to any fault in the technique, or whether due to some other local condition. During the above mentioned period they had operated upon 926 patients for tonsils and adenoids. Of these 5 were under 1 year; 12 between 1 and 2 years; 43 between 2 and 3 years; 47 between 3 and 4 years; 47 between 4 and 5; 54 between 5 and 6; 36 between 6 and 7; 114 between 7 and 10; 120 between 10 and 15; 83 between 15 and 20; 142 between 20 and 30; 93 between 30 and 40; 38 between 40 and 50; 15 between 50 and 60; 6 between 60 and 68; in 71 the age was not given. Of these 794, or 86 per cent. were given a general anesthetic, and 132, or 14 per cent., were operated with local anesthesia. The operative technique was the same whether done under general or local anethesia. The selection of the anesthetic was mainly a matter of choice on the part of the patient and operator, with the exception that in acute lesions of the kidney and in cases of severe chronic bronchitis and arrested tuberculosis, they deemed local anesthesia preferable to general. Suction was employed in all stages of the operation to keep any escaped blood from entering the larynx. The tonsil was seized with the forceps, the anterior and posterior pillars were carefully freed from the capsules, a cold wire snare was placed around the partially freed tonsil, and dissection completed by closure of the wire loop. Immediately following the excision a rounded gauze sponge on a sponge holder was placed in the fossa to arrest hemorrhage. At the end of two or three minutes it was removed, and all bleeding points grasped with an Allis forceps; if on removing the clamp there was a recurrence of the bleeding, it was their custom latterly to ligate the bleeding vessel or vessels. Each tonsillar fossa was ascertained to be absolutely dry before proceeding to the excision of the adenoids, and was carefully inspected, as were also the enucleated tonsils, to see that no particle of tonsil tissue was left in situ. While performing the operation they had frequently noted in children discrete lymph nodes in the anterior or posterior pillar of the fauces, and sometimes in the velum or soft palate, well anterior to the tonsillar fossa. It was impossible to remove these lymph nodes without removing so much of the anterior or posterior pillars, as the case might be, as to result in a very marked shortening and contraction of the pillars, which was most undesirable. They had watched the course of these lymph nodes and found that at times they disappeared while at other times they continued to hypertrophy similarly to the lymph nodes that were found in the posterior pharyngeal wall. When so located that they might be mistaken for rehypertrophy of the tonsillar tissue, they might be differentiated from a regeneration of the tonsil tissue by the absence of crypts or lacunæ peculiar to tonsil tissue. These lymph nodes were not infrequent in children under five years of age, were rarer in children over five years of age, and seldom seen in adults. The amount of hemorrhage in children under six years of age was seldom more than a dram per tonsil, and the average amount of hemorrhage in adults was less than six drams per tonsil. The hemorrhage was usually less when local anesthesia was employed than when a general anesthetic was administered.

Adenoidotomy.—Dr. Coakley stated that they had coined this term to indicate the fact that they removed the excessive amount of lymphoid tissue in the nasopharynx in contraindication to its complete removal, as would be indicated by the term adenoidectomy. They found it impossible to remove all traces of lymphoid tissue from the vault of the lateral wall of the nasopharynx, and judging from the results of other operators they were no more successful than the writers. Owing to the imperfect removal of adenoid tissue it was never possible to state definitely that there might not be a sufficient hypertrophy of the tissue that remained to produce symptoms either referable to obstruction, sepsis, or infection, extending through the Eustachian tube to the tympanum. The instruments used for adenoidectomy were the LaForce adenotome, followed by Gottstein's curette, and the use of punch forceps to excise the lymphoid tissue below the Eustachian tube on the lateral wall of the pharynx. The amount of blood lost in operations on adenoid tissue was usually more than from the two tonsils combined. *Post-Operative Care.*—Following operation patients were put to bed, kept on their right side as far as possible in Sim's position, so that in case there was any bleeding from either tonsillar fossa or nasopharynx, it was easily noticed by the nurse as coming from the mouth or nose. As regards reaction to the operation there was a marked difference between children and adults, older children and adults being considerably more prostrated by the operation than children under six years of age. *Hemorrhage.*—Dr. Coakley distinguished two types of hemorrhage, namely, one that came on shortly following the operation, usually within twelve hours, while the other came on several days later. The proper treatment of hemorrhage following operation was the rapid removal of the clot, so that the bleeding point might be discovered, an artery clamp placed on the point and a ligature applied. He had never seen a case where this treatment did not arrest hemorrhage. Hemorrhages occurring later in the course of healing were due to the dislodging of the exudate in the tonsillar fossa involving the vessels whereby thrombosed vessels were reopened. In these cases the bleeding was usually controlled by pressure, or by clamp and ligature if necessary. In the series of cases under consideration 15 had had hemorrhages from their tonsillar fossæ requiring to be controlled. There were six males and nine females; the youngest 13 years of age, the oldest 45. Dividing them into classes, nine bled within twelve hours after the operation. Of the 140 patients over 40 years of age operated upon only 2 had had hemorrhages, or 1.3 per cent. There were two instances of hemorrhage from the adenoids; in one case plugging was required while the other ceased spontaneously.

Children who were subject to attacks of acidosis while their tonsils were *in situ*, were frequently similarly affected postoperatively, and their recovery from the operation was delayed according to the degree of the acidosis. They had had but one case of otitis media develop immediately after tonsillectomy. Similarly, they had had but one case of lung abscess following tonsillectomy. This case was reported in detail; it was generally agreed by the physicians and surgeons in charge of patient that an infected thrombus dislodged from a vessel in the tonsillar fossa was carried into the right lung as an infective thrombus. Aspiration of blood at the time of operation could not in any way be considered a real factor in this case. *Deaths.*—So far as they could ascertain but six patients had died since operation. These cases were reviewed in detail. One case of particular interest was that of man, 36 years of age, referred by Dr. Richard Weil and Dr. Theodore Janeway. He had a slight chronic cardiac valvular lesion. His physicians were desirous of getting him into better physical condition, and to avoid all sources of infection that might result in acute infective endocarditis, advised having his tonsils removed, since they were congested and contained much detritus. He made an uneventful recovery from the

operation. Dr. Simon Flexner reported that he could cultivate no bacteria from the tonsils. During two years following the operation the patient had several attacks of acute rhinitis and pharyngitis. About two and a half years after the operation he was found to have an infective endocarditis and bacteria were found in the blood. It was rather remarkable that this patient who had his tonsils enucleated mainly because Dr. Janeway felt that it might be a prophylaxis against acute endocarditis, did develop the disease after his tonsils were enucleated. In another patient, a boy 12 years of age, whose infected and hypertrophied tonsils were removed in the hope that a glycosuria might be improved thereby, it was very evident that the removal of the tonsils improved his general condition and prolonged his life. In two of these six patients the immediate cause of death was not known. In all it was at a date remote from the operation and apparently in no way related to the operation of tonsillectomy.

Dr. EDWARD L. PRATT continued the analysis of these 926 cases, reviewing the replies to the questionnaire sent to these patients. Of the 926 questionnaires sent out replies were received from 689 patients, or 74.4 per cent.; 60 were returned as not found, and 172 received the paper but did not reply. They had reviewed the answers to each question separately and had formulated their statistics exactly from the replies of the patients. To the first question "What caused you to have your tonsils removed?" forty different causes were given by the patients for the removal of their tonsils and adenoids; 244 patients, or about 41 per cent of the cases who gave a definite answer to the question, had had the operation performed for the relief of local throat conditions. Of these patients there were 9 who reported no benefit resulting from the operation because they continued to have frequent sore throats; all were re-examined and in only *one* case was any tonsillar tissue found. In the other 8 cases the cause of the continued throat trouble was traced to other conditions. There appeared to be no question that lymphoid tissue capable of hypertrophying to a considerable degree might be and often was present extracapsular to the tonsils, and might cause a pharyngitis which the patient described as sore throat or tonsillitis. Of the 36 cases giving diseased tonsils as the chief complaint, there were no unsatisfactory reports. The same was true of the 35 cases of hypertrophied tonsils. Quinsy was the next most common etiological factor, occurring in 18 cases, only one of which reported any attacks after the operation. In this case a piece of tonsil was found in the right fossa which might have been responsible for the quinsy. There were four cases of diphtheria and one of angina which reported no recurrence of the condition. Enlarged cervical glands were the chief cause of operation in 27 cases; of these 19 reported entirely successful results; 4 stated that the gland was reduced in size, and 4 reported no benefit. In 3 of the latter pathological examination showed the glands to be tubercular. There were 42 cases in which ear trouble was given as the cause for removal of the tonsils and adenoids. Of 15 who complained of impaired hearing or deafness, there were 9 who reported their hearing as restored to normal, and 6 who were not benefited; these had had badly impaired hearing for some years. There were 35 cases which sought relief from mouth breathing; of these 7 were operated for adenoids and 28 had both tonsils and adenoids removed. Of the total number, 31, or 88 per cent, were entirely successful; 2 partially successful and 2 reported no relief. One of these had a sinus infection and in the other there had been a recurrence of adenoid tissue. About 20 per cent of the answers to the first question gave some systemic condition as the chief cause for the operation. There were 23 different conditions given, of which Dr. Pratt reviewed the more important ones in detail. There were five heart cases. In one of these, a boy of 10 years, with a slightly enlarged heart and a systolic murmur, whose cardiac condition incapacitated him from participating in the usual activities of boys, following the removal of his tonsils the murmur disappeared and he was now able to indulge in all the sports of a normal boy. Two other cardiac cases reported that they were free from symptoms; the remaining two were improved but not entirely free from symptoms. There were 5 cases of acute nephritis with albuminuria and in all these cases all symptoms disappeared after operation. Of 5 cases of asthma, one was relieved, one improved and 3 reported no benefit. Of two diabetic cases, both failed to receive any benefit so far as the diabetes was concerned, though in the case to which Dr. Coakley had referred removal of the tonsils and adenoids unquestionably improved the general condition and joint pains from which the patient had long suffered entirely disappeared. Of 15 cases whose chief complaint was a general run down condition, 8 of whom were children and 7 adults, the results were completely successful, often as startling to the parent as they were gratifying to the operator. Other questions which were included in the questionnaire, the replies to which were reviewed, were as follows: 2. How many previous operations on your tonsils? 3. Has your general health been better, worse, unchanged since your operation? 4. Had you suffered from rheumatism before operation? If so, are you better, worse, or unimproved? 5. Had you had measles, scarlet fever, whooping cough, St. Vitus dance, chicken pox, or diphtheria, before operation? after operation? 6. Had you ever had quinsy before your last operation? After it? 7. Did you suffer from frequent colds in the head before operation? If so, are they less frequent now? 8. How frequently did you have any trouble with your ears (ear ache, discharging ears) (a) previous to operation? (b) after operation? 9. Has anything led you to believe your tonsils have grown again? If so, what? 10. Did you have a general anesthetic (ether) for your operation? or a local anesthetic (cocaine)? 11. Will you please state in a general way your impression of the results of the operation on your tonsils and adenoids? In analyzing the answers to the remaining questions, Dr. Pratt said he was aware that the results were subject in some cases to a varying degree of error. This was especially true of the third question. There were many factors which might influence the general health of the patient after any operation, so that it was hard to estimate, with any degree of accuracy, whether any given operation was a primary, or merely a contributing cause to the result. However, of the 689 cases returning questionnaires all but 14 answered this question and 85 per cent. reported that their general health was better; 12 per cent. reported that it was unchanged, and 3 per cent. stated that it was worse. Of 107 cases reporting that they had had rheumatism before operation, 71 per cent. reported as better and 20 per cent. as unimproved. Of 46 cases in which rheumatism was the primary cause for the operation, only 17 per cent. reported unimproved. Of 53 cases having attacks of quinsy prior to operation, only 2 had attacks after operation. Six hundred and eleven patients made statements as to their general impression of the results of the operation. Of this number 529 reported satisfactory results; 82 unsatisfactory results. The unsatisfactory results were carefully gone into to ascertain the exact reason why they were unsatisfactory. This did not mean that the entire 82 cases were not benefited. One group of 30 cases was not satisfied because the condition for which they sought relief was not improved. These conditions included phlebitis, sore throat, colds, and recurring attacks of pharyngitis. Another group of 24 cases was displeased not because the condition for which they sought relief was unimproved, but apparently because they had expected too much of the operation. The occurrence after tonsillectomy of such conditions as eczema, headache, neuralgia, nervousness, etc., etc., in patients whose complaint at the time of operation was in no way related to such conditions could hardly be considered as just grounds for condemning the operation. They concluded that about 6.8 per cent. of these patients had just reason for dissatisfaction. In concluding, Dr. Pratt said their experience led them to believe: 1. Where the pathological condition of the tonsil warranted its removal, age was a negligible factor as it would be in any other common surgical operation. 2. Hemorrhage either during or after operation, could and should be controlled according to the same surgical principles as governed its control elsewhere in the body during a surgical operation.

3. A well done tonsillectomy and adenoidectomy caused a marked lessening of the acute infections of the upper respiratory tract, and lessened the tendency toward attacks of acute middle ear infections. 4. The percentage of successful and partially successful results in cases of rheumatism justified the removal of tonsils in cases where the tonsils were proved to be diseased, and where the elimination of other sources of infection had failed to give relief. 5. Cardiac and renal cases associated with infected tonsils should be studied with care before advising tonsillectomy, lest serious results ensue. In properly selected cases associated the percentage of successful results justified the operation. 6. Tonsillectomy was not to be recommended as a panacea for all ills, but when the operation was well done, with the view of relieving a definite pathological condition the percentage of successful results was most gratifying.

Dr. SAMUEL A. BROWN stated that this analysis by Dr. Coakley and Dr. Pratt presented a number of interesting facts. First was the direct and definite way Dr. Coakley had answered so many of the questions constantly coming up before them as clinicians relative to the advisability of operating upon the tonsils at different ages and the possibility of hemorrhages and other factors of that type. This presentation could not but be helpful to those who met these problems frequently. Dr. Brown stated that he was particularly interested in the case of cardiac trouble in which the symptoms disappeared after tonsillectomy. He said he could not conceive that this was a true endocarditis. It seemed to him that there must have been a relative murmur or a functional murmur associated with anemia. The question after all was whether there was not a toxemia that was causing the muscular deficiency of the heart and that was what they were interested in when they removed the tonsils. They all saw cases in which the muscular efficiency was improved, the general condition improved and toxemia eliminated after the removal of the tonsils. In relation to the rheumatic cases, it was his experience that they should advise the removal of the tonsils, reserving the possibility that the rheumatism might be associated with infection other than that of the tonsils. But one should not be over-enthusiastic as to the results of removal of the tonsils in cases of rheumatism and should explain to the family that improvement could be expected only where the tonsils were the foci of infection causing the symptoms. Dr. Brown asked Dr. Coakley to express an opinion as to the advisability of removing the tonsils in the presence of acute exacerbation of symptoms, and also whether tonsillectomy was advisable during active rheumatic fever, in the persistent cases.

Dr. WALTER L. NILES said it seemed to him that this very interesting analysis brought forward the important question of the relation of tonsillectomy to general health from a new angle, that was from the standpoint of the patient; the patient had been allowed to judge of the results of the operation, and after all that was something that must be taken into consideration. He thought that the very gratifying results in this series of cases must have been due to the excellent technique employed. He was interested in the subject from the standpoint of the systemic condition, and especially interested in the report of complete freedom from pulmonary abscess. He agreed that in the one case of empyema the operation of tonsillectomy could not be held responsible. He had come to regard pulmonary abscess as a not infrequent sequel of tonsillectomy and had seen at least a dozen cases in which tonsillectomy seemed to have been the etiological factor. Pulmonary abscess was of such serious significance that it must be taken into consideration both in deciding as to the advisability of operation and the type of operation. Keeping the throat free from blood during the operation was undoubtedly an important factor in avoiding this complication. The symptoms of lung abscess did not manifest themselves until four or five days after the operation and were very frequently taken for tuberculosis. At Saranac he had seen a number of cases of lung abscess that had been diagnosed as tuberculosis. As an aid in the diagnosis of lung abscess the *x*-ray did not tell very much, but in the presence of such symptoms after tonsillectomy had been performed one should be very suspicious of pulmonary abscess. With reference to the heart conditions, he thought this presentation emphasized the importance of the tonsils as a source of infection and doubted whether in many cases the endocarditis was not present at the time the tonsillectomy was performed; he imagined the infection must be present in the heart valves many years before the symptoms developed, but in cases of endocarditis the removal of the tonsils was a preventive of the further entrance of bacteria from that source. He believed that cases of acute rheumatic fever were often benefited by tonsillectomy and were to be regarded somewhat differently from those of subacute bacterial endocarditis. He was much interested in the kidney cases reported and fancied they brought home a lesson that should be regarded more frequently. One saw many cases of early nephritis, not interstitial nephritis but parenchymatous nephritis, without hypertension but with edema, and in a number of such cases he had seen the symptoms clear up after tonsillectomy. The small number of cases reported this evening in which tonsillectomy had apparently benefited cases of early nephritis bore out his feeling on this subject. As to chronic arthritis it was well to remember that Dr. Coakley did not advise tonsillectomy simply because the patient had an arthritis. He thought a great deal of the dissatisfaction with the operation was because the patient had not been carefully studied and a reasonable determination made as to whether or not the tonsils were infected. Some of Dr. Coakley's cases illustrated the fact that many foci of infection other than the tonsils might be present and lead to secondary systemic manifestations, so one should not take chronic arthritis and regard only the tonsils, but should take into consideration other foci of infection. In concluding, Dr. Niles said he felt that this discussion would aid in determining the probable outcome of a tonsillectomy, and emphasized the importance of studying the individual case and not performing a tonsillectomy lightly.

Dr. WOLFF FREUDENTHAL said the information they had received to-night was surely very interesting. He could only congratulate Dr. Coakley and Dr. Pratt on their very excellent results; 86 per cent of good results after tonsillectomy was remarkable and he was sure it was entirely due to the skill of Dr. Coakley and Dr. Pratt. His own experience went back over thirty years and he did not dare hope that his results were as good as those mentioned this evening. He took a peculiar standpoint in regard to tonsils. Dr. Coakley reported that he did tonsillectomy in children under three years of age. Dr. Freudenthal did not do a radical operation on children of that age unless the tonsil was absolutely hidden behind the pillars. Otherwise he did an old-fashioned tonsillotomy. He felt that perhaps he was the only man in New York who continued to do that operation, but the old practitioners were not men who acted wholly without reason and they had some very good results too. His experience was that it was better to take out only that part of the tonsil that interfered with breathing when the child was so young, even at the risk that one might have to do a complete tonsillectomy later on. He left as much tissue *in situ* as he could for many reasons. A few years ago he had published a paper in which he spoke of the destruction of the physiological function brought about by complete removal of the tonsils and also of the destruction of a great deal of the pharyngeal function. The speakers did not mention the detrimental effects of tonsillectomy which were also to be taken into consideration. When one sees the large amount of scar tissue in some patients following tonsillectomy one is not surprised that these patients should suffer more with throat symptoms than before the removal of the tonsils. He had seen many lesions, as, for example, adhesions of the anterior and posterior pillars and had seen almost the entire soft palate adherent to the posterior wall of the pharynx so that it was difficult to free it. Many of these patients came from other clinics to his department. Quite a number in private practice. It might be recalled that Dr. Fleischman came out with the idea that the tonsils had a certain function in stimulating the leucocytes and were *glands of internal secretion* comparable to

the thyroid and adrenals and secreted a distinct substance which was discharged into the oral cavity and into the blood stream. Many who performed tonsillectomy had numerous failures, since few were as successful as the men here to-night. Indeed, the results were sometimes very bad. Dr. Freudenthal asserted he had seen rheumatic fever, tuberculosis, and other diseases develop in spite of the fact that the tonsils were taken out and all the teeth as well. In view of this his advice was "Be very slow in taking out the tonsils and all the teeth."

Dr. HAROLD HAYS said these two papers brought out a number of points that should cause them to think considerably. Two points were of particular importance. In view of the large number of successes following tonsillectomy reported to-night he was wondering how many patients would refuse operation because of the new treatment by the *x-ray*. He feared that a great many persons would delay having the operation done where it was absolutely necessary and would submit to *x*-ray treatment in spite of the very inconsequential proof so far as the results of *x*-ray treatment were concerned. Another point was that he had seen a number of failures following tonsillectomy where a secondary operation had to be performed and Dr. Coakley and Dr. Pratt reported having seen similar failures. From this we ought to understand that although tonsillectomy was considered a simple operation it should not be performed by everybody, but only with circumspection and by those with experience. It would have been interesting if Dr. Coakley and Dr. Pratt had said something of how the throats looked in the cases in which the operation had failed. One saw many malformations as a result of improperly performed tonsillectomies that were never reported. As to hemorrhage, it did play a large part in tonsillectomy, and for that reason in many patients the coagulation time of the blood was not taken. He had found that one could not place much reliance upon the coagulation time of the blood as an indication of the possibility of hemorrhage. He had operated upon patients in whom the coagulation time was high, even ten or twelve minutes, and had encountered no severe bleeding, while in others in whom the coagulation time was four or five minutes he had had trouble. Nevertheless, he felt that in bleeders one should take the coagulation time of the blood. Dr. Hays said he was impressed with the results reported in the mouth breathers in this series of cases. As a rule one could not promise too much in the way of relief to mouth breathers by removal of the tonsils, for many times nasal breathing was not as good as it should be, and the condition present was such that it could not be corrected by tonsillectomy and adenoidotomy but only by orthodontia. Dr. Hays said he used to claim that if the anesthetic were properly given lung abscess would not follow tonsillectomy, but unfortunately he had seen a case of lung abscess in which the greatest precautions had been taken. He felt that lung abscess might be due not only to the aspiration of blood but to lack of resistance in the lung tissue. However, under general anesthesia with suction he was confident that there were fewer abscesses than formerly occurred when lung abscess had not been diagnosed and recorded. They saw in this series, 14 cases in which the chief complaint was general malaise, which was relieved by tonsillectomy. In this connection Dr. Cotton's report of the relief and improvement of various mental conditions following the removal of a foci of infection was interesting. Such evidence forces one to the conclusion that many systemic conditions were due to foci of infection in the tonsils, teeth, and intestinal tract, and frequently the general condition was improved by removal of the tonsils. He thought it would be very difficult for most men who were doing this operation to present statistics as successful as these. The subject had been handled, Dr. Hays thought, in a most illuminating manner.

Dr. BEAMAN DOUGLASS said he had not expected to discuss these papers but felt that he ought to say something in corroboration of the views of the speakers, presented in such an unusual way and with statistics on a sufficiently large number of cases to enable them to draw conclusions. The papers contained no surprises, or at least very few surprises to the man who saw many tonsil operations. It conveyed to the minds of those who had never made a statistical study confirmation of their general experience as to what happened in these cases. One point in this report, he did not understand and that was how a vasomotor rhinitis could be cured by tonsillectomy unless the adenoids were removed. The other parts of the papers were very satisfactory and coincided with the results of the work at the Post-Graduate Hospital, yet the conditions under which this work was done in a hospital were very different from those in private practice. In the Post-Graduate Hospital they had several classes of men doing the operations. They had the high-class men who were doing private work and the postgraduate students, yet among 1,500 operations they had had but three instances in which there was hemorrhage sufficiently serious to call the house surgeon from his room to the ward. They had had no pneumonia cases and only two deaths, both occurring in the service after operation by high class specialists. One was said to be due to morphine and the other to hemorrhage not stopped in time. There was a strange uniformity in the two series of cases, yet in the Post-Graduate series they had high-class specialists, a great many mediocre operators and many students. He had wat hed the cases very carefully and was surprised that they had so little trouble and that they were so free from postoperative complications. He felt that there was nothing to say against tonsillectomy or the new way of performing the operation. Dr. Freudenthal said he was probably the only one doing the old operation of tonsillotomy, and no one else ought to do it. Since the introduction of tonsillectomy it was perhaps conservative to say that three million tonsillectomies had been done in the United States, and many on whom the operation was performed had had time to grow to adult life and older ages and one did not hear either directly or indirectly any bad word for the tonsil operation. Though it was not a minor operation it was largely devoid of danger and gave good results. Probably the percentage of good results reported this evening was a conservative one.

Dr. CHARLES HENDEE SMITH stated that one of the remote effects of tonsillectomy was its influence on the child's weight. Everyone has seen children who came to the dispensary a day or two after an operation on the tonsils with circles under the eyes and a foul breath and who were taking no food. If one weighed these children before and after the operation it would be found that they had sustained a considerable loss of weight. If weighed regularly it would be found that these children recovered their normal weight very slowly. He had seen a child lose as much as ten pounds and take three or four months to recover it. By keeping the child in bed a week, until his appetite returned, he did not burn up his reserve fat as fuel and recovered quicker from the effects of the operation. At the end of a week the loss would be regained and the child go on to uninterrupted recovery. When tonsillectomy was performed on members of the cardiac and nutrition classes at Bellevue they made it a rule that the child must be kept in bed for a week. He believed that was the most important factor in the after care of tonsil cases.

Dr. COAKLEY, in closing the discussion, said Dr. Brown had brought out the point as to the occurrence of acute articular rheumatism after tonsillectomy and also in regard to operation upon cases of acute articular rheumatism that had not yet recovered from the acute attack. So far as the first problem was concerned, rheumatism immediately after tonsillectomy, he had record of but one case. That patient had acute articular rheumatism associated with mild polyarthritis and acute tonsillitis; she recovered from the tonsillitis and practically recovered from the polyarthritis. In this case, Dr. Coakley said he was urged to operate as soon as he thought wise because she was a cook and a very necessary person in the household to which she belonged. At the operation one of the tonsils came out very nicely and cleanly; it was impossible to get the other tonsil out completely and a portion was

left in the supertonsillar fossa. A short time after operation, perhaps forty-eight hours later, there was a mass in that tonsillar fossa larger than before the patient was operated upon and the acute polyarthritis became much more severe. It seemed that the connection between these two occurrences was very great. In no instance in which there was complete tonsillectomy had he ever seen acute polyarthritis or rheumatism follow the operation. As to the second question, he had often felt that the time to take out the tonsils in polyarthritis, where the tonsils were *in situ* and diseased, was during the acute stage. The nearest he had come to that, however, was in scarlet fever cases at the Rockefeller Hospital where they were trying to work from the tonsils as a source of infection. Dr. Flexner had asked him to take out the tonsils so that he could examine them for organisms. He performed tonsillectomy on six or eight patients in whom the temperature was between 102° and 103° F., and the tonsils were full of exudate. In no case was there albumen in the urine as a result of the anesthesia, and in most of the cases the temperature dropped following the operation. It was quite possible that in certain cases of acute polyarthritis tonsillectomy might be effective in improving the condition; he would like to see it tried. As to the patient who Dr. Janeway thought might be getting chronic endocarditis, he was an important man in the community and they were afraid he might develop an endocarditis. He did the tonsillectomy and the man did not die until three years after the operation. It was barely possible that he had the organisms locked up in his heart at the time of the operation, but Dr. Janeway thought his chances of escaping endocarditis were better if his tonsils were removed. As to Dr. Freudenthal's experience with tonsillotomy, he did not see why one was justified in leaving one-half of an infected tonsil any more than he would be justified in leaving one-half the appendix in doing an operation on that organ, and saying that if the operation was not successful the remainder of the appendix could be taken out later. He agreed that tonsillectomy in children two or three years old was a more difficult operation than in adults as the capsule was exceedingly thin and one must be extremely careful not to destroy the anterior or posterior pillar, but with care it could be done in children as well as in adults. If part of the anterior or posterior pillars were destroyed and one attempted to do a tonsillectomy later the result was not pleasing. Dr. Hays had spoken of the coagulation time of the blood. He agreed with Dr. Hays that one could not place a great deal of reliance upon the coagulation time as an indication of the amount of hemorrhage that would occur at operation, but when a patient stated that he was a bleeder it was wise to take the coagulation time. Dr. Hays expressed regret that reference was not made in the papers to deformities following operation. He regretted to say that they sometimes did get deformities, and they occurred a little more frequently in the posterior than in the anterior pillar, but if one was careful and dissected the posterior pillar first and then the anterior pillar deformity would not often occur. One could not say that if the patient had been operated upon before, for in secondary operations one did not always get as good results as in primary operation, he saw no reason why lung abscess should always be due to the inhalation of blood, why it might not be of the infarct type. During the operation the parts were in motion and there was a certain amount of tearing loose of blood vessels and clots and an infarct might get into the lung. There were perhaps more infarct cases than we thought; that was a matter that should be looked into. In regard to the loss of weight following tonsillectomy in children to which Dr. Smith had referred, there was less trauma in the dissecting operation than in many operations done with instruments of the Sluder type, and there was less interference with the ability to take food. They kept all their patients quietly in bed for forty-eight hours, following operation; this lessened the danger of taking cold as well as being an advantage in other respects. Even the child with diabetes on a restricted diet lost only a quarter of a pound following tonsillectomy. The children they operated upon did not lose weight to any extent.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting Held May 25, 1921.

THE PRESIDENT, DR. GEORGE MORRIS PIERSOL, IN THE CHAIR.

The Rat Menace of the United States.—Dr. S. B. GRUBBS, Surgeon, U. S. Public Health Service, read a paper in which he said that there was undoubtedly a rat menace; a menace to life and a menace to business from bubonic plague which had been spreading over the world during the past twenty-five years. There was, on the other hand, an economic loss from rats that was going on each day and night. For our purposes it was sufficient to recognize that we had to deal with the gray, or burrowing rat, and the black, or climbing rat. All rats possessed an intelligence that was most uncanny, certain highly developed special senses, and a strength and persistence that overcomes many difficulties. Generally speaking, both kinds of rats were scattered all over the civilized globe, were intimately associated with man, and fed upon everything that he produced as food for himself and his domestic animals. The gray, or Norway rat, was the pirate rat of the story books. While not nimble, he had managed to board ships and to travel to all ports. He killed for the love of killing, as well as for food; what he wanted he took; he feared no animal his size. He was short of tail, broad of jaw and back, heavy and muscular; good at digging, but poor at running or climbing—let others run or climb when he walked forth. He lived where he chose, which was in burrows, or near the ground, in or under a protecting structure. Under the term black rat were included *Mus alexandrius* and *M. rattus*. This one was more slender, graceful, and agile. His tail was long. He could run well and climb wonderfully, but, being no match for the gray rat, thrived in the walls and roofs of houses and such places as his enemy could not go. All rats were prolific breeders. Beginning at two months, females would produce as many as eight to ten litters a year, each consisting of eight to twelve young. Fortunately rat infant mortality was large, and a decreased food supply would reduce both the number of litters and the number of young in each. Restricting the nesting places also decreased the number of litters, but had slight effect upon the number in each. In addition, restricted nesting places meant restricted protection, so that in the struggle for existence the young and weak ones were driven out or killed by the stronger ones. It was upon the restriction of rat food and of rat nesting that all our efficient and economical measures must be based. Rats had diseases, some of which might be transmitted to man. Rat leprosy, infective jaundice, and rat-bite fever might be largely of academic interest, but bubonic plague was an every-day danger and an economic loss. With the beginning of this century plague invaded the western hemisphere, appearing in San Francisco in 1900 and in Enseñada and Mazatlan, Mexico, in 1902. Coming from the other direction in 1912, it reached Porto Rico, probably from the Canary Islands, and shortly after it appeared in Havana and New Orleans. During 1920, plague was found in Pensacola, Florida, and in Galveston and Beaumont, Texas. In February of this year it occurred in Porto Rico once more. In those places that were solidly and permanently constructed, such as many European ports, or where the disease was fought by a vigorous anti-rat campaign, as in the United States, it might be eradicated, but where buildings were harbors and efforts were divided between rat control and prevention of human cases the disease usually became endemic. He believed the chief value of rat catching was to locate rat infection in advance of human cases, and so they examined every rat they could get, and also insisted on permanent ratproofing, not only of infected, but of all buildings. Plague was a hard disease to exclude, and difficult to eradicate when once admitted. The experience in New Orleans, where human plague reappeared after eighteen months without finding any rat infection—April, 1917, to October, 1919—during which time 50,000 rats were examined, must make us timid about declaring the infection definitely eradicated, and should cause us to

advocate that in places once infected, rat control and surveys in some form should continue indefinitely. Dropping for a moment this public health aspect of the rat question, the speaker said, he would consider the harm that the healthy rat does. A large amount of damage was done by rats seeking food or gnawing apparently for the mere fun of it. Everyone who stored merchandise, except under exceptional circumstances, would find rat losses of some kind if he would investigate. Captains and managers of vessels who were alert to save, usually knew that rats played havoc with certain cargoes, and were, therefore, glad to have their ships fumigated, although this might cost them $100, in addition to several hours' delay. All they asked was that the fumigation should get the rats and stop claims against them for rat damage to cargo in transit. The greatest loss was from the consumption and waste of food products. The best general estimate that we had now was that there was one rat for every city dweller and ten for every one living in the country, and that the food of each rat cost approximately half a cent a day, or $1.83 per year. Primary rat-proofing, made as a part of the original construction, added but slightly to the expense. If this was neglected, however, so that it became necessary to alter buildings already up, the expense was considerable. We know from experience that quarantine alone could not be entirely relied upon. We needed to stress the advantage of rat-proofing in advance of infection. It would be good business for every port, and in fact, for every inland city, to require new construction to be rat-proof. Such requirements would gradually convert our rat-ridden seaports into places where rats could easily be controlled, where rat losses would be small, where plague would have a small chance of getting started, and where, if it did, it could rapidly be exterminated.

The Rat in Relation to Philadelphia's Food Supply.—Dr. HENRY D. MARTIEN, of Philadelphia Bureau of Meat Inspection, read this paper, in which he said that in the recent rat campaign special investigations were conducted of conditions, laying stress upon places where foodstuffs were stored or handled. This class of buildings included food warehouses, animal abattoirs, chicken keeping and slaughtering establishments, markets, meat markets, fish and oyster houses, grocery stores, bakeries, restaurants, and fertilizing plants. These places afforded rats a most bountiful ration to feed upon, and further provided most favorable conditions under which they bred. Dirty, careless merchants, buildings with defective walls or foundations, broken wooden floors, unscreened ventilators; doors, windows, and transoms left open during the night; doors and windows in poor repair, defective sidewalks, privy wells, defective plumbing and storing of boxes, barrels, and papers in cellars and vacant rooms were some of the conditions which were encountered in his routine inspection work. It was these conditions that he strove to correct. Another most important feature of the rat control work in regard to food supply was the surrounding environment, such as stables, poorly built buildings, carelessness in handling foods, and in the disposal of waste material. The chicken keeping and killing establishments were a very common place of rat infestation, as it was almost always the rule that rats and chickens went together. The rat-proofing of a chicken establishment was a difficult problem for the following reason: The price of poultry and the margin of profit made the owners of these places most reluctant to institute necessary improvements to keep out the rat. Dr. Martien said he was not advocating high prices, but if the shopkeeper put his building in proper sanitary condition and kept it so he must work on a greater margin of profit. The abattoir was possibly the worst infected place that presented itself to-day, on account of the fact that a vast amount of material that was at hand to feed upon and also on account of presenting most favorable breeding places. The pens in which the live stock were kept afforded most favorable breeding places as well as a shelter; stables which were in almost all cases located near these abattoirs provided favorable breeding places. Some of the means employed in Philadelphia's deratization work were briefly: Anti-rat propaganda scattered by means of anti-rat editorials and publications in the daily newspapers; pamphlets and bulletins scattered by the Department of Public Health and the United States Health Service. An educational campaign must be conducted, depicting the proper methods of rat-proofing. The erection of buildings with rat-proof foundations should be encouraged. The building laws for new buildings and repair work should be corrected. Wooden floors should be replaced with cement, defective concrete floors should be patched with concrete; defective openings around pipe and rat holes should be sealed with cement; all ventilators, doors, windows, transoms, and skylights should be screened. In short, we should build out the rat. In rat-proofing a building the following conditions must be considered: Ground area, walls, ceilings, garret roof, dead space in general, ventilators, abandoned sewers, doors, windows, outside piping, water and sewer piping, down spouts, wiring, and air and light shafts. A very small detail might be overlooked whereby a rat-proof structure might become badly infested. In the educational work several classes and conditions were met with: First, the man who was progressive in business and was eager to comply with the city's request; 10 per cent. of the merchants could be placed in that class. Second, a group who were willing to comply, but on account of ignorance were continually a health menace. A large majority of the people with whom the speaker came in contact would fall in this class. Third, those who were in business for gain only and cared not for any law. In conclusion he pointed to some of the results attained in Philadelphia's rat work. Today they had under control the rat situation in the wholesale fish market, and one might say the market was clean. In the cold storage plants the rat was finding a hard time to exist, and the same statement applied to the abattoirs. The educational campaign had been most successful as a large majority of the food handlers had been convinced that the rat was a health menace, a pest, and a destroyer of property, not only by eating food products, but also by setting fire to property.

Bubonic Plague: The Rat Situation in Philadelphia.—Dr. C. Y. WHITE, director of the Laboratory of Hygiene of Philadelphia, read this paper, in which he stated that he had been in three campaigns in Philadelphia, one starting in the latter part of 1912-13, then in 1914, and in the fall of 1920. The earlier campaigns were undertaken for the purpose of determining whether bubonic plague was present in Philadelphia or not. They made a strenuous effort to capture as many rats as possible. In the last campaign, while they tried to get rats, the chief message was through an educational campaign. To help this educational proposition along the department prepared a great number of circulars. These pamphlets were placed chiefly in business houses and in places where they tried to educate those who came in direct contact with the rat. It was pretty well accepted at present that plague was carried from place to place, or port to port, or locality to locality by the rat, but the actual infection to the human being was due to the rat flea. In the plague situation in the south it was demonstrated very well, or at least surmised, that the flea had a great deal to do with this dissemination. Dr. White said the department had examined about 12,000 rats. They found 22 leprosy rats in those dissected in the three campaigns. Dr. White said he felt that in Philadelphia, in order to keep up the rat campaign, it should be made a part of the function of the Public Health Department. He thought Dr. Grubbs would agree with him that it was impossible to expect the community to rid a place the size of Philadelphia of rats. As fast as one killed them off probably so fast they would breed, but a community the size of Philadelphia should know the condition of its rat population and that could be done by surveys, probably not quite as extensive nor quite as large as the United States Public Health Survey suggested. They suggested about 10 per cent. survey, which would mean in Philadelphia about 200,000 rats.

The cost of the rat survey in the South had been from $1 to $1.30 per rat. In the rat campaign in Philadelphia, last fall, while it was not as extensive as the southern rat campaign, they were able to catch a rat and dissect it for about 30 cents. So they felt

that if they were to have connected with the department here a small rat corps, consisting of probably three or four rat catchers and an inspector, they could accomplish much in one year as to the rat population. Then if they found an infested rat, devoting the employment of the larger corps to clean up. We should strive to induce Congress to give our Public Health Service in Washington a bigger appropriation, so that they could go to the root of the matter and handle the situation outside of the United States. The keystone to the whole subject of the plague situation was to keep out the rats rather than to try to get them out after they came in.

Dr. JOSEPH MCCRACKEN of Canton, China, said that he would like to say a little bit about what they had found in the Orient. He was fortunate enough to be in Canton, where this plague was supposed to have begun, and sitting on the wall of the city of Canton, in one hour he counted over 200 coffins going out of that one gate to be buried on the hills back of the city. When it was considered that there was a population about the size of Philadelphia all within an area of not more than two miles square, and where the roofs were so close one could almost step from one house to the other and realize that there was absolutely nothing done in that whole city for the sake of health, not anything whatever by the government, and very little by any individual, and when one realized that there was practically no sewer system in that city, and that the place was riddled with rats as well as infested with the bubonic plague, it almost made one wish one had a diver's suit to go down and walk on the streets; and yet, after living in Canton six or seven years, he knew of only one foreigner who had died of plague. That foreigner was kind enough to pick up a patient afflicted with bubonic plague, and he vomited almost into the helper's face, and he died of plague a few days later. Most of the talk was about bubonic plague, and that was the general kind they had in the South. He knew of a very few cases in the southern part of China which was pneumonic; it was bubonic. He was of the opinion that there were two separate diseases. It had generally been their idea that the bubonic plague was carried by the rat and the pneumonic possibly by some other animal similar to, but not a rat. In northern China a recent statement by Dr. Wu, in charge of the plague in North Manchurian Mission, and Dr. Young, a practitioner in Pekin, showed that the first cases were bubonic and then the pneumonic form developed. That was certainly not brought out in the epidemic which existed in China a few years ago. It was of the pneumonic type. The mortality in the bubonic form was very much less than that of the pneumonic, which was absolutely fatal; so fatal was it that Dr. McCracken remembered that when they had an epidemic in northern China some of the southern nurses volunteered to go up and help in the plague, and eleven went up. After nine had died with pneumonia one of those left came home with high fever and headache, and thinking his time had certainly come, he told the Chinese boy in the hotel where he was living what to do with his trunk and fur overcoat, and then he took a big dose of medicine and thought it would be the last of him. He woke up the next morning, feeling much better, but when he looked for his trunk and fur overcoat they were minus. The boy had skipped. In the houses of the native Chinese, where one had very little authority over the people, it was almost impossible to carry on anything like a thorough campaign.

Dr. SENECA D. EGBERT said that he felt that the point that was made in regard to the development of the idea of cleanliness in many of our stores and other establishments in the city was most important. The survey he made a year and a half ago had impressed upon him that many, many places where food was handled and dispensed were beyond the pale of cleanliness. The people who managed them did not know what cleanliness meant. There was a tremendous amount of campaigning that we all might do. We could help our patients to feel that they must carry on this campaign of education. In other words, we could insist upon cleanly food coming from cleanly places and refuse to deal with places that were not cleanly.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

Denver, January 4, 1921.

ANATOMY.

1. Define and locate lateral sinus, fissure of Sylvius, anterior fontanelle, conjunctiva, and mitral valve.
2. Describe the shoulder joint with overlying structures and muscular attachments in the immediate vicinity.
3. Define hernia. Describe minutely the anatomical course of the inguinal and femoral types.
4. State definitely the result of cutting these nerves in the living subject: radial, facial, and recurrent laryngeal.
5. Give attachments, action, and nerve supply of the following muscles: adductor longus, gastrocnemius, triceps femoris, sternomastoid, and temporal.
6. Describe the thyroid gland.
7. Discuss the anatomical divisions of the small intestine.
8. Describe the location where the femoral artery is most readily tied. What structures must be cut to secure it at this point?
9. Describe Hunter's canal and its contents.
10. Describe in detail the ligaments of the uterus.

PHYSIOLOGY.

1. Describe the digestion of a meal of beefsteak and potatoes.
2. Does alcohol possess a food action, and on what do you base your answer?
3. What digestive changes takes place (1) in the small intestine, and (2) in the large intestine?
4. State the origin, nature, and destination of the glycogen of the liver.
5. State the origin and the various uses of lymph in the human body.
6. Describe the changes that take place in secreting glands during activity and rest.
7. State the influence of the blood circulation on the secretion of the urine. How would the division of the renal nerves affect the secretion of urine?
8. Define afferent, efferent trophic, inhibitory, motor, and vasomotor nerve fibers.
9. How is accommodation in the eye accomplished?
10. What nerves control the action of the heart?

CHEMISTRY

1. Define atomic and molecular weight.
2. Differentiate (*a*) A mass of matter; (*b*) a chemical compound; (*c*) an elementary body. Give example of each.
3. What are chlorides, bromides, and iodides? Give examples.
4. What is common salt? (*a*) How is it obtained? (*b*) Give the manner in which it acts when used in freezing mixtures.
5. What foods undergo lactic acid and butyric acid fermentation?
6. Explain the principal action of yeast.
7. What organic acids are present in vegetables and fruit?
8. How does urea originate in the body? In what morbid conditions is the amount diminished and in what increased?
9. Write the chemical equation of the reaction occurring when sodium bicarbonate is administered for hyperacidity of the gastric juice.
10. Give a reliable test for bile in the urine.

ANSWERS.

ANATOMY.

1. *The lateral sinus* is a venous blood channel situated between the periosteal and meningeal layers of the dura mater of the brain. It extends from the internal occipital protuberance to the jugular foramen.

The fissure of Sylvius is situated on the outer surface

of the cerebral hemispheres. It is a deep fissure of the brain beginning on the outer side of the anterior perforated space, and extending outward to the lateral surface of the hemisphere.

Anterior fontanelle is a diamond shaped space found in the skull of infants; it is situated between the parietal and frontal bones.

Conjunctiva is the mucous membrane covering the anterior part of the eyeball and reflected upon the inner surface of the eyelids.

Mitral valve is the valve protecting the orifice between the left auricle and left ventricle.

2. The *shoulder-joint* is an enarthrodial joint formed above by the glenoid cavity of the scapula and below by the head of the humerus. Its ligaments are glenoid, coraco-humeral, and capsular. The glenoid surrounds the edge, deepens the glenoid cavity, and is continuous above with the long head of the biceps tendon. The capsular ligament, extensive and loose, arises above it from circumference of glenoid cavity behind the ligament, is attached below to the anatomical neck of humerus, and is pierced by tendons of two or three muscles. The coraco-humeral, or accessory, is a fibrous band which extends obliquely downward and outward from the coracoid process to the anterior part of great tuberosity, strengthening the capsular ligament. A *synovial membrane* lines the joint, and forms the bursa under the subscapularis. It is reflected round the tendon of the biceps, and lines the bicipital groove. The *nerve supply* is from the circumflex and suprascapular nerves. The *arteries* are branches of the anterior and posterior circumflex, and the suprascapular.

The *muscles in relation with the joint*, are: above, the supraspinatus; below, the long head of the triceps; in front, the subscapularis; behind, the infraspinatus and teres minor; internally, the long head of the biceps. The deltoid covers the joint in front, behind, and externally.

3. A *hernia* is a protrusion of part of the parietal peritoneum, through some weak point in the abdominal wall, in the form of a sac; in this sac may be a portion of the omentum, small intestine, or occasionally some other abdominal organ.

The forms of inguinal hernia are:

(1) *The Direct*, in which the hernia does not occupy the inguinal canal, but leaves the abdomen to the inner side of the deep epigastric artery, through the space known as Hesselbach's triangle. There are two forms of this variety: (*a*) the hernia may escape between the epigastric artery and the obliterated hypogastric artery; (*b*) or it may escape between the obliterated hypogastric artery and the outer edge of the rectus muscle.

(2) *The Indirect* or *Oblique*, in which the hernia occupies, wholly or in part, the inguinal canal. An *oblique inguinal hernia* may pass into the scrotum or labium majus, when it is called *complete*; or may be retained in the inguinal canal, when it is called *incomplete*, or a *buboncele*.

COVERINGS OF INGUINAL HERNIA.

DIRECT.	INDIRECT.
Skin.	Skin.
Superficial Fascia.	Superficial Fascia.
Intercolumnar Fascia.	Intercolumnar Fascia.
Conjoined Tendon.	Cremasteric Fascia.
Transversalis Fascia.	Infundibuliform Fascia.
Subperitoneal areolar tissue.	Subperitoneal areolar tissue.
Peritoneum.	Peritoneum.

Femoral hernia leaves the abdomen through the femoral ring and descends into the femoral canal; this canal is funnel-shaped, is about half an inch in length, and ends at the saphenous opening. Femoral hernia is always *acquired*, and has a sac. Its course is first vertical, then forward, then upward over Poupart's ligament. Its coverings, from without inward, are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum. The neck of the hernia is situated at the femoral ring; to its outer side lies the femoral vein, and to its inner side is Gimbernat's ligament; in front of it is Poupart's ligament, and behind it are the pubis, the pectineus, and the pubic portion of the fascia lata.

4. *Section of the radial nerve* may cause a slight loss of sensation on the thenar eminence and the back of the hand and fingers.

Section of the facial nerve causes a paralysis of muscles of facial expression on the affected side; the face on that side is smooth and free from wrinkles; the eye cannot be closed; the nostril cannot be dilated; the mouth is drawn to the unaffected side, and food passes between the cheek and the teeth; attempts at whistling show distortion of the face. There may also be loss of the sense of taste in the anterior two-thirds of the tongue on the affected side.

Section of the recurrent laryngeal nerve causes hoarseness, and loss of voice; or the voice is weak, and altered in character.

5. ADDUCTOR LONGUS. *Origin:* Front of pubic bone where the crest and the symphysis meet. *Insertion:* Into the linea aspera of femur, between the vastus internus and adductor magnus. *Action:* Adductor of the thigh, and flexion of thigh on pelvis. *Nerve supply:* Obturator nerve

GASTROCNEMIUS. *Origin:* Upper and back part of inner condyle, and outer surface of external condyle and adjacent part of back of femur. *Insertion:* Into lower and back part of os calcis. *Action:* Extensor of foot, it raises the heel; it also flexes the femur on the tibia. *Nerve supply:* First and second sacral nerves.

STERNOMASTOID. *Origin:* Upper and outer part of the anterior surface of the manubrium sterni, and upper surface of the clavicle at its sternal end. *Insertion:* Outer surface of mastoid process of the temporal bone, and outer part of the superior curved line of the occipital bone. *Action:* To flex the head to the same side as the muscle; the two acting together flex the head on the thorax and also raise the upper thoracic wall in forced inspiration. *Nerve supply:* The spinal accessory nerve and a branch from the cervical plexus.

TEMPORAL. *Origin:* Temporal fossa and inner surface of temporal fascia. *Insertion:* Into coronoid process of inferior maxilla. *Action:* It raises the lower jaw, and aids in drawing the jaw back. *Nerve supply:* Inferior maxillary division of fifth cranial nerve.

6. The *thyroid gland* is situated on the sides and in front of the upper part of the trachea, and extends upward on each side of the larynx. The *thyroid gland* consists of two lateral lobes and an isthmus: it is situated at the front and sides of the neck. The lobes extend from about the middle of the thyroid cartilage to the fifth or sixth tracheal ring; the isthmus generally covers the second and third tracheal rings. The lobes measure about $2x1^{1}/_{4}x^{3}/_{4}$ inches; the gland usually weighs about one ounce. *Blood supply:* Superior and inferior thyroid arteries, with thyreoidea ima; and superior middle, and inferior thyroid veins. *Nerve supply:* Branches from the inferior laryngeal nerve, and from the middle and inferior cervical ganglia of the sympathetic.

7. The *small intestine* is situated in the abdominal cavity. It begins at the pyloric end of the stomach, in the epigastric region and ends at the ileocecal valve in the lower part of the right lumbar region. Its average length is about 23 to 25 feet. It is divided into three portions, the duodenum, the jejunum, and the ileum. The duodenum is the first part of the small intestine, it is about ten inches long, and extends from the pylorus to the left side of the body of the second lumbar vertebra. The jejunum and ileum form the coils of the small intestine and are covered by the great omentum; they form the remainder of the small intestine, the upper two-fifths being the jejunum and the lower three-fifths the ileum; there is no line of demarcation between these two parts. The coils of the jejunum and ileum are suspended from the posterior abdominal wall by the mesentery.

8. *The femoral artery is readily tied* at the apex of Scarpa's triangle, which is four to five inches below Poupart's ligament. *The structures severed*, are: Skin, superficial and deep fascia, and the femoral sheath.

9. *Hunter's canal* is situated in the middle third of the thigh, extending from the apex of Scarpa's triangle

to the opening in the adductor magnus muscle. It is covered over by an aponeurosis which extends from the vastus internus to the adductor longus and magnus, and contains the femoral artery, femoral vein, and internal saphenous nerve. Externally, the canal is bounded by the vastus internus; and internally by the adductor longus and magnus.

10. THE LIGAMENTS OF THE UTERUS. (1) *Broad ligaments*, which extend outward on each side from the side of the uterus to the side of the pelvis. (2) *Rectouterine ligaments*, which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments*, which extend from the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) The *ovarian ligaments*, which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) The *uterosacral ligaments*, which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac synchondrosis.

PHYSIOLOGY.

1. *Beefsteak* consists of protein and fat; *potatoes* consist mainly of carbohydrate, with a little protein. In the mouth the ptyalin of the saliva changes the cooked starch into dextrin and maltose. In the stomach, the proteins are changed into proteoses and peptones. In the small intestines the proteins are still further reduced to polypeptides and aminoacids (by the trypsin of the pancreatic juice); the cooked starches are converted (by the amylopsin) into maltose; and the fats are emulsified and saponified.

2. "The exact value of alcohol as a food, broadly considered, is uncertain. Recent experiments, carefully made on man, however, clearly show that when moderate amounts of alcohol are ingested, the alcohol is burned up in the body—*i. e.* oxidized like any non-nitrogenous food. The potential energy of the alcohol is transformed into kinetic energy, and consequently alcohol is to be considered as having some food value. It may, therefore, be classified with the non-nitrogenous foods. Further, as a non-nitrogenous food, alcohol may replace an isodynamic amount of fat or carbohydrate in the diet without change in the balance of income and outgo. Alcohol serves to protect body protein and fat from oxidation *i. e* like a typical non-proteid food it diminishes the oxidation of tissue protein by being itself oxidized. These facts, however, do not imply that alcohol is necessarily a desirable food or that it is physiologically economical. It is to be remembered that, prior to its oxidation in the body, alcohol may produce deleterious effects of various kinds, more than counterbalancing any gain which may result from its oxidation. It may likewise give rise to changes, either directly or indirectly, in the various metabolic processes of the body, which must of necessity influence more or less its value as a food. Alcohol has a direct and an indirect influence upon the secretion of gastric juice. In this direction it acts as a stimulant. It likewise stimulates the secretion of saliva."—(Chittenden in *Reference Handbook of the Medical Sciences.*)

3. *In the small intestine:* Proteids are turned into proteoses and peptones, and further reduced into polypeptides and aminoacids; starches are converted into maltose; fats are broken up and emulsified or saponified. *In the large intestine* the same processes of digestion may *continue*, but nothing new (in the way of digestive activity) is started.

4. Glycogen is chiefly formed from the carbohydrates. The liver cells act upon the dextrose into which the carbohydrates have been converted by the action of the ptyalin and amylopsin. This may occur by dehydration, but the exact process is not known. At a subsequent period the glycogen is transformed into dextrose and is returned to the circulation. Hence the blood of the hepatic veins contains more sugar than the blood of the arteries, and these latter more than the blood in the veins (except the hepatic). It is the generally accepted view, but it is denied by Pavy, and the whole subject is in a state of uncertainty.

The destination of glycogen: It is converted into sugar (dextrose), is given off to the blood, and is finally oxidized in the tissues.

5. *Formation of lymph:* There are three main theories: (1) Ludwig's theory, or the filtration theory, coupled with osmotic changes between the lymph and blood; (2) Heidenhain's theory of lymphagogues; and (3) Starling's theory of the permeability of the capillary walls. The subject is summed up by F. A. Bainbridge as follows: "Lymph formation is not a secretory process, but is brought about by purely physical processes, namely filtration and osmosis; and the factors concerned in its production are (1) the capillary pressure, (2) the degree of permeability of the capillary walls, and (3) the metabolic activity of the tissues. There is no reason to suppose that in health the permeability of the capillaries alters, and therefore the formation of lymph is increased chiefly by variations in the first and third of these factors."

Function of lymph: (1) it conveys nutriment to all cells not directly reached by the blood; (2) in the intestines, it absorbs nutrient material (chiefly fat) and pours it into the blood stream for distribution; (3) it takes certain waste matters to the blood to be later eliminated by the lungs, kidneys, and skin.

6. The salivary glands may be taken as an example of secreting glands, and the following changes have been observed in them:—"In a section of a *submaxillary* gland, which is *resting*, that is, has not been secreting for some time, the cells are large and nearly fill the alveoli. Each cell has a nucleus placed near its outer end and surrounded by a small amount of protoplasm which is granular and stains readily. The rest of the cell is quite clear and transparent and stains with great difficulty if at all. Since the material composing this clear part of the cell is of the nature of mucin, the submaxillary gland is spoken of as a *mucous* gland. In similar sections of the *parotid* gland, also in the *resting* condition, the cells are smaller than in the alveoli of the submaxillary gland. Further, the nucleus lies near the middle of each cell, and the whole cell is extremely granular and stains fairly easily. The body of each cell is composed of albumin and is free from any trace of anything like mucin; hence the parotid is known as an *albuminous* gland. After these glands have been *secreting* for hours, as the result of stimulating the nerves supplied to them, the appearance of their cells is greatly changed. The cells of the *submaxillary* gland are now smaller; the nucleus is nearer the center of each cell and the whole cell stains readily. In the *parotid* gland the cells are similarly smaller, the nucleus more distinct, and the cell substance stains more readily than in the condition of rest. If instead of taking sections of the hardened gland a piece of the fresh parotid be examined, it will be seen that at *rest* the cells are full of granules throughout; while after *activity* the granules are fewer and lie near the inner end of the cells." (From Huxley's *Elementary Physiology*).

7. The secretion of the urine is to some extent dependent on the blood circulation. Increase in the amount of blood, increase in the blood pressure or in the action of the heart will result in an increase in the secretion of urine. *Section of the renal nerve* causes a dilatation of the renal arterioles, with increase in the amount of urine secreted, but there is no increase in the solids.

8. An *afferent* nerve fiber is one that conducts nerve impulses from the periphery towards the brain or cord.

An *efferent* nerve fiber is one that conducts nerve impulses away from the brain or cord, and towards the periphery.

A *trophic* nerve fiber is one that nourishes a tissue or organ or part of the body.

An *inhibitory* nerve fiber is one which conveys a nerve impulse which results in the lessened activity of a part.

A *motor* nerve fiber is one which causes contraction of a muscle.

A *vasomotor* nerve fiber is one which conveys nerve impulses to the muscular coat of a blood vessel.

9. *"Mechanism of Accommodation.*—The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the choroid and relaxing the suspensory ligament; this diminishes the tension of the lens cap-

sule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines." (May's *Diseases of the Eye.*)

10. The nervous mechanism consists of an inhibitory and an acceleratory supply. In addition, there are various intrinsic ganglia in the heart which are supposed to be responsible for the heart-beat. The *cardio-inhibitory* center is connected with the nucleus of the vagus in the floor of the fourth ventricle, and the fibers from it pass to the heart along the vagus nerve. Its function is to slow the beat of the heart. It is sometimes known as the anabolic center, because it lessens the rate and force of the heart and so allows time for building-up processes (anabolism). If the peripheral end of the cut vagus is stimulated, the heart is slowed and may be entirely stopped. It is a tonically active center, that is, it acts continuously, so that the simple cutting of the vagus takes off the brake and lets the heart run away.

The *cardio-accelerator* center is also in the floor of the fourth ventricle. It acts through the sympathetic fibers which descend in the spinal cord and leave it through the anterior roots of the first and second dorsal nerves, and go thence to the cardiac plexus. This center keeps up the rate of the heart beat.

CHEMISTRY.

1. *Atomic weight* is the weight of the atom of an element as compared with the weight of an atom of hydrogen.

Molecular weight is the weight of a molecule of a substance (element or compound) as compared with the weight of an atom of hydrogen.

2. *An elementary body* is a substance which cannot by any known means be split up into other, dissimilar, substances; Example, nitrogen.

A chemical compound is a substance made up of two or more elements, chemically united, and in definite proportions; Example, nitric acid.

A mass of matter is an aggregation of molecules resulting from the union of two or more substances, whether elements or compounds or mixtures, and without any regard to quantities or to chemical union; Example, a lump of earth.

3. *Chlorides*, are binary compounds containing chlorine, or salts of hydrochloric acid; Example, sodium chloride NaCl.

Bromides are binary compounds containing bromine, or salts of hydrobromic acid; Example, sodium bromide, NaBr.

Iodides are binary compounds containing iodine, or salts of hydriodic acid; Example, potassium iodide, KI.

4. *Common salt* is sodium chloride, NaCl.

It is *obtained* from salt deposits in the earth, and is then purified. It is also obtained by evaporating brine.

Freezing-mixtures: The absorption of heat in the passage of bodies from the solid to the liquid state has been used to produce artificial cold. This is effected by mixing together substances which have an affinity for each other, one of which at least is a solid. Chemical affinity accelerates the fusion, and the portion which melts robs the rest of the mixture of a large portion of sensible heat, which becomes latent. If the mixture cannot supply sufficient sensible heat, the latter will be absorbed from all surrounding substances. When ice is mixed with salt in the proportion of two parts of the former to one of the latter, the ice is rapidly melted, the rapid thaw involving a rapid disappearance of heat. If the mixture surrounds a liquid at the ordinary temperature, and if care is taken to prevent the ice from obtaining the necessary heat from other sources, the heat will be abstracted from the liquid, and in a short time its temperature will be so reduced that it will become frozen. The temperature obtained by the mixture of ice and salt, or snow and salt, is about 0° F.

5. *The following undergo lactic acid fermentation:*—Levulose, lactose, dextrose, invert sugar, cane sugar and maltose.

The following undergo butyric acid fermentation:—Levulose, maltose, dextrose, invert sugar, cane sugar, and lactose.

6. The principal chemical action of yeast is the splitting up of glucose into carbon dioxide and ethyl alcohol:—

$$C_6H_{12}O_6 = 2C_2H_5OH + 2CO_2$$

Other chemical changes also occur, such as the formation of small quantities of glycerol, succinic acid, and propyl, butyl, and amyl alcohols.

7. *Organic acids present in vegetables and fruit:*—Citric, malic, tartaric, oxalic.

8. *Urea formation.* The greater part of the urea produced in the body is formed in the liver. The liver cells form the urea from two sources: (1) The larger amount, produced by the liver cells, is derived from the amino-acids which have been absorbed from the small intestine, and which are not required by the tissues; this constitutes the *exogenous* urea. (2) The smaller amount, produced by the liver cells, is derived from the ammonium carbonate, which is the outcome of nitrogenous catabolism, and which is derived from the tissues; some is also produced by the action of the uricolytic enzyme upon uric acid; this constitutes the *endogenous* urea.

9. $NaHCO_3 + HCl = NaCl + CO_2 + H_2O$.

10. Test for *bile in the urine:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

(*To be continued.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION
Alabama*	S. W. Welch, Montgomery	Montgomery
Arizona*	A. Martin, 207 Goodrich Building, Phoenix	Phoenix
Arkansas	T. J. Stout, Brinkley	Little Rock Nov. 8
California	C. B. Pinkham, Sacramento	Sacramento Oct. 17
Colorado	David A. Strickler, Empire Building, Denver	Denver
Connecticut*	R. L. Rowley, Hartford	Hartford
Delaware	H. W. Briggs, Wilmington	Wilmington Dec. 13
Dist. of Col'bia	E. P. Copeland, Washington	Washington
Florida*	W. M. Rowlett, Tampa	Jacksonville Aug. 1
Georgia	C. T. Nolan, Marietta	
Idaho*	L. E. Hansen, Wallace	Boise Oct. 4
Illinois	F. C. Dodds, Springfield	Chicago
Indiana	W. T. Gott, Crawfordsville	Indianapolis
Iowa	G. H. Sumner, Des Moines	Iowa City
Kansas	H. A. Dykes, Lebanon	Topeka Oct. 11
Kentucky	A. T. McCormack, Louisville	Louisville
Louisiana	E. W. Mabler, New Orleans	New Orleans
Maine	F. W. Searle, Portland	Portland
Maryland	J. McP. Scott, Hagerstown	Baltimore Dec. 14
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston
Michigan	B. D. Harrison, 205 Whitney Building, Detroit	Lansing Oct. 11

Miscellany.

SOME MEMENTOS AND THEIR CUSTODIANSHIP IN THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

THE College of Physicians of Philadelphia has become the repository of some most interesting mementos of persons of great accomplishments in medical science. These are Jenner, Rush, Pasteur, Lister, and the two Curies. The mementos are in a case in the cabinet of the College and are at present under the custodianship of Dr. William Henry Welch of Baltimore.

The idea of a custodianship of these mementos was conceived and put into effect by Dr. Robert Abbe of New York, eleven years ago. At that time he came into possession of the watch of Dr. Benjamin Rush, the donor requesting that he bequeath it to the most distinguished member of our profession whom he might consider to represent the spirit and qualities eminent in Dr. Rush, and by him to be passed on to successive custodians as the years went by. It was justly thought that it would be considered a mark of distinction thus to be one of a chain of honored names perpetuating the renown of Benjamin Rush.

In the MEDICAL RECORD of November 5, 1910, Dr. Abbe outlined this scheme and announced his choice of the first custodian. He wrote:

> In seeking a name for the first custodian I have, by elimination, chosen one whom I think you will agree with me has added to scientific research, an untiring spirit of work, a broad human helpfulness, patriotism, and literary culture—Dr. Weir Mitchell. It is especially fitting that Dr. Mitchell is a Philadelphian and an ex-president of the College of Physicians of which Dr. Rush was a founder. Dr. Mitchell agrees with me that the idea of perpetuating this memorial is most happy, and he accepts the trust, and agrees to nominate a successor, and to have the watch preserved in the cabinet of the institution as one of its most valuable assets.

As a companion piece to be kept with the watch, Dr. Abbe had made a book of blank pages finely bound, in which he wrote a brief biographical statement as representing the estimate of one of the profession in New York, followed by one from the pen of Dr. Weir Mitchell of Rush's own city. Following this is a collection of photographs and engravings of all the existing portraits of Dr. Rush, with such autograph letters as could be obtained. Then comes the letter presenting the watch and inaugurating the scheme by the lady from whose hands it came to Dr. Abbe. On succeeding pages are to be portraits of successive custodians of the watch, with a statement of the essential reasons of choice, as well as the letter of acceptance of the trust.

Dr. Mitchell chose Dr. Simon Flexner of New York as his successor in the custodianship, and the latter, after three years, passed on the honor to Dr. Welch.

The cabinet now contains the following articles: The watch, above mentioned, and also a silver shoe buckle, set with brilliants, worn by Dr. Rush and presented by his great-grand-daughter, Mrs. Catharine Rush Porter. An inkstand used by Edward Jenner, and bequeathed to the College of Physicians by Weir Mitchell. A small case of instruments used by Joseph Lister and secured for the cabinet through Sir Rickman Godlee, whose wife was a daughter of Professor Syme of Edinburgh and a niece of Lord Lister. The fourth souvenir is a model of a tartrate crystal which Pasteur made, labeled, and mounted with his own hands, for use in demonstrating the nature of crystals formed in wine fermentation. The model was a gift to the College from Calmette of the Pasteur Institute, and was brought over by Dr. W. W. Keen. The latest, memento is an instrument, devised by Professor Pierre Curie and used by him and Mme. Curie to determine the strength of electron discharge from radium. By means of this instrument, called the quartz-piezo-electric apparatus, M. Curie illustrated his discovery that crystalline substances, when compressed or expanded, emit electrons due to the strain put upon them. This instrument was presented to the College by Mme. Curie in person, in response to a request by Dr. Abbe for a souvenir of her work. In presenting the apparatus Mme. Curie placed her hands upon it to insure it "freedom from homesickness in this beautiful land."

A fund has been established by Dr. Abbe, who is an honorary fellow of the College, to maintain and enhance the collection and to perpetuate the idea of honoring the great men of past achievement who have developed the science of medicine.

The "Nonliftable" Man or Woman.—The daily press has for the past six months or more contained frequent accounts of men and women who could not be raised from a recumbent position on the floor by an outlay of strength sufficient to raise several fold the dead weight. For some reason the subject received no attention in the leading medical weeklies, although the subject is not a new one. Last April the matter came up at a session of the Society of Comparative Pathology in France, and a brief account is found in the April 27 issue of *La Presse Médicale*, xxix, 34. The paper was read by Azoulay with the title "Physiological and Psychological Considerations upon the Nonliftable Man." Reference is made to an article by Ruffier in the January number of *Physis*, a scientific journal. The subject of the test is at a psychological advantage over the lifter. The one to be raised is said to grasp the lifter about the carotid region in bracing himself for the test and this could work to a disadvantage in several ways in compressing the large vessels and nerve trunks. Again the torsion of the right wrist of the lifter weakens the total lifting power of the arms. In discussion Moret relates that he tried to lift a woman weighing 48 kilos and his inability to do this was apparently the result of the placing by the woman of her index finger on his cervical region. Before this maneuvre he was able to lift her, but the mere application of the finger as mentioned, although no pressure was exerted, seemed to prevent a repetition of the act. The woman had also taken his wrist in her hand, but the author does not say whether force was used. Legrand had had the same experience and believes that the nervous state of the lifter is the leading factor. Demonchy said that if a sheet of paper is placed between the finger and carotid it has an inhibitory effect on the phenomenon.

CONSTITUTION AND THE PERSPECTIVES OF PATHOGENESIS OF TODAY.*

BY JOHN C. HEMMETER, M.D., PHILD., LL.D.,

BALTIMORE, MD.

PROFESSOR IN THE UNIVERSITY OF MARYLAND.

THE time is ripe for an historiographic research of the ideas and conceptions which leading thinkers in medicine have held concerning the nature of the bodily constitution.

In the study of the causes of disease, we have become absorbed in the wealth of modern investigation and literature concerning mainly two great disease producers. *First, invading microorganisms* and other living infectious agents, and *secondly, chemical substances* arising within the body or entering the body from without. As a third group of causes, we have become familiar with the excitatory or inhibitory influences exerted by an unphysiological nervous system. I do not say pathological nervous system for this expression would range the third group into one or other of the first and second groups, for a decidedly pathological nervous system is either the consequence of an infection or of the deleterious influence of some chemical substance of an exogenous or endogenous origin; but when I say unphysiological, I mean a state in which the central and peripheral nervous system is capable of functioning normally but at times functions in a manner which, while it is not pathological, yet it is not in perfect coordination with the normal performances of the other organs. There is an erethism of the central nervous organs which, while not physiological, cannot be classified as pathological. And yet, this erethism may lead to abnormal states in other organs.

Disregarding the diseases which are admittedly inherited, these three pathogenetic ideas dominate all of our thinking concerning the nature of disease. In this comprehensive view of causes, the medical mind has, however, not given due consideration to another factor in disease production which overtowers in colossal importance all these three causes together; and this factor is the *human constitution itself* upon which the pathogenetic factors just mentioned exert their various influences.

It might be argued that in the very brief scheme of diseases mentioned I have not referred to abnormalities caused by trauma; for example, diseases caused by pressure or violent and mechanical changes of position; seasickness; aviator's vertigo. But this leads to a great many other diseases which are not due to infection nor chemical causes; for instance, the diseases due to hyperthermia or extremes of temperature in general; exposure to great heat and cold; the effect of radiating energy as a disease-producing cause—sunlight, Roentgen rays, radium emanations, etc.; the effect of electricity as a cause of morbidity; of atmospheric pressure and atmospheric humidity. All of these disease factors in their finality will express themselves in chemical or physical changes, or in injury to the nervous system, secondary to such changes, and thereby come under the brief classification before mentioned.

Constitution and Disposition.—Inasmuch as these two terms are frequently confused, sometimes mistaken for synonyms, and even erroneously defined, it will be necessary to give a precise meaning of the terms before proceeding.

These two terms are erroneously defined in the "National Dictionary of Medicine," by John S. Billings and collaborators. They are erroneously defined in part, in the last edition of Webster's Dictionary. In "Hallische Universitätsreden" for 1916, the eminent clinician, E. Adolph Schmidt, states that "constitution" and "disposition" mean the same thing.

Definition of Constitution.—The degree in which the organism is capable of overcoming difficulties; of enduring deprivation; the greater or lesser resistance against exogenous injurious influences; the ability to compensate and equalize detriments that have already been caused by mild disease-producing factors.

Definition of Disposition.—Receptivity to disease; inherent sensitiveness to pathogenic factors; facilitation for reaction to injurious influences.

Disposition is a quality; constitution is a quantity.

In human pathology, the two conceptions are in reality antagonistic. A strong constitution, meaning increased resistance, is as a rule coexistent with decreased disposition; and a weak constitution, meaning lessened resistance, is coexistent with increased disposition.

Constitution is a variable disease factor, and, according to Martius, is the measure of the resistance of the organism toward pathogenic influences and is composed of the changeable state of individual organs of the body, and therefore constitution varies individually and is different according to different conditions of the organs. The general or total constitution is thereby separated into a sum of partial constitutions. We can therefore conceive of constitution quantitatively, but disposi-

*President's address at the annual meeting of the American Therapeutic Association, Washington, D. C., June 3, 1921.

tion should be considered only qualitatively. Only those factors go to make up the constitution which come to the organism during intrauterine life.

It is certain that human individuals of different classes and animals of different species are attacked by certain pathogenic factors with greater or less facility, while others of the same class of individuals remain free under the same external and internal conditions. Those that are attacked are designated as "disposed'; those that remain free are called "immune." Classes and species may be equally disposed or sensitive to a certain bacterial poison, but of these, we sometimes find one sensitive to another poison, while the other is immune to the second poison. For example, horses and heifers are equally sensitive to tetanus poison; but for diphtheria, heifers show no disposition, but horses, a very marked disposition; human beings are sensitive to the toxins of scarlet fever and measles, but animals show no disposition to these infections.

We have proceeded far enough to illustrate that constitution and disposition are two entirely different things. For further information concerning these factors see P. Bourcy, "Prédisposition et immunité," in Bouchard's Traité de pathologie générale, T. I. Paris, 1895. From this instructive work one can learn that a series of factors influence and accompany both the constitution and disposition. For example, race, age, sex, the momentary general health of the individual, but, above all, a long series of external conditions which have not yet been exactly defined because they cannot be ascertained in the human being and can only be controlled in disease produced experimentally. To illustrate this point, and also to emphasize the traditional idea of the causation of a human disease, let us summon before our mind's eye the development of a pneumonia. There are three factors necessary in its pathogenesis: (1) A peculiar quality of the body, the constitution; (2) a specific living microorganism, pneumococcus; (3) a sum of contemporaneous external and internal conditions.

Hitherto the medical mind has been tyrannized by an inverted perspective of disease pathogenesis; it has conceived the infecting microorganisms or the toxin, or the physical force as the exclusive factor in the production. This is a total disregard of the immense importance of the human constitution in its innumerable varieties and of the human disposition. This inverted view has been due to an overestimation of the importance of bacteriologic factors, and in its final analysis, is due to the greater facility and control which laboratory methods of culture and staining and experimental infection with microorganisms offer to the bacteriologist. The more important and far-reaching factor—the human constitution—has either been disregarded or it has been taken for granted that it was completely understood. As a matter of fact, this very human constitution and disposition, which are spoken of in the writings of Aristotle and Hippocrates, and all medical writers since then, are just beginning to be understood in their basic component elements within the last ten or fifteen years. The reasons for the imperfect comprehension of constitution and disposition are to be sought in the almost insuperable difficulties which they oppose to investigation; for not only must the clinical scholar familiarize himself with the details of biochemistry, the effect of physical forces, the relation of the specific personal anatomy of human beings, but he cannot avoid the study of the specific psychology of the human subject that he is dealing with in each special instance.

If, therefore, I recommend a method of observation for the nature of disease which bases it on at least three factors, it is because this mathematical perspective is valuable as a basis for philosophical clinicians in their struggle against the one-sided, rigid method of clinical thinking which has become a form of monopoly of medicine of to-day.

The laboratory worker, like a chemical experimenter, can form his own conditions, lay down and preserve by weight and measure all of the chemical, bacteriological and other factors that enter into his investigation; in short, mathematical circumscription can be made to control his research. But in such complex relations as the natural development of a disease the application of mathematical principles is not feasible and, therefore, it is absurd to speak of the disease as due to a single cause and its effects. In place of this it would be more promising for precision in clinical medicine if any pathological happening or event were deduced from the coaction of a sum of various etiological factors. This is the view which Martius advocates in "Pathogenese innerer Krankheiten," 1909, and which has received the approval of Verworn and Hansemann.

We can make a beginning by singling out from the many more or less important conditions necessary to produce a disease two basic factors: First, the cause; and second, the releasing moment. By *cause*, in our new method of thinking, we must understand the constitution and disposition of the human being in whose body the potential energy of the disease phenomena and the curative processes will play their rôles; it is the endogenous factor. But the *releasing moment* or factor is the microorganism, toxin, or physical force, as the case may be, and which is specific in each disease.

It will be immediately recognized that this manner of thinking is exactly the reverse of what we have been accustomed to up to the present time. "Pathological conditions and processes," said Virchow, "are physiological processes under difficult circumstances," and just as two normal human beings are never perfectly alike, much less can two cases of the same disease be perfectly alike. There are very few releasing factors, or exogenous causes, as you could call them, which produce exactly the same consequences in all human beings. Perhaps the mechanical trauma and extremes of temperatures may provoke the variable resistance of different individuals in a closely similar manner. But we soon discover with other physical causes (electricity, atmospheric pressure, radioactive substances, etc.) that the individual variation has to be reckoned with more and more.

We must not overlook that in infections it is the effect of toxins that we are dealing with more than the mechanical damage of the tissues by microbes. There are human beings who are so sensitive to definite toxins that they react to the most infinitesimal doses with the severest symptoms, while the majority of human beings do not react to the same toxins in any measurable degree. The medi-

cal systems of the older times called this "idiosyncrasy" and attributed it to a peculiar composition of the juices of the individual. More modern medicine speaks of this hypersusceptibility as "anaphylaxis" and "allergy."

The disengaging or releasing factors not of microbic origin and which are still frequently used and not understood are such words as "*catching cold*," *overexertion, exhaustion, disturbance of nutrition.* They seem to be common household words in medicine and yet not understood. Only in the last year have explanations of the process of catching cold been brought forward. It is asserted by H. Schade (Untersuchungen in der Erkältungsfrage, etc. *Münchener med. Woch.*, lxvii.) that catching cold is not an infection nor a neurosis, but an increase in the density of the tissues caused by the cold and a reduction of their elasticity. This can be measured by an instrument—the elastometer. The colloids of the tissues appear to be undergoing a precipitation which is not demonstrable histologically. The effect of cold can express itself in a cold-neurosis; for instance, of the kidney, bladder, digestive tract. The disposition to catch cold has arisen from hyperdomestication, especially from neglect of usage of the vasomotors of the skin. Especially disposed are the persons with a high degree of moisture in the skin—a general increased water percentage of the tissues; in short, the ancient lymphatic and erethic constitution. It is plainly evident that we are beginning to understand what catching cold means.

The physical changes of the tissues in catching cold are reversible, but if the intensity of the cold is very great, the "colloidity" of the injured tissues remains permanent. Such conditions have been called "cold-gelosis," because normally the almost liquid lymph of the tissues assumes a consistency like that of gelatine in the injured area. Schade believes that such "colloidity" may occur in muscles, joints, ligaments, nerves, even in the mucous membranes; in one case described by Freitag the cold-gelosis was observable in the cornea in the form of a clouded, opaque area. This condition was reversible and disappeared when warmth was applied.

A similar article by S. Colm—"Leitsätze einer Säftelehre"—explains the movements of the caryolymph by reciprocal physical and chemical reaction between certain colloids of the cell and certain molecules of alkali; the colloids he speaks of as existing in the intracellular substance are albumin and lecithin; the protoplasm is mainly composed of albuminous substance. The lecithin enters the construction of the cell membrane. The functions of life are attached to these two substances together with certain potassium and sodium salts. He describes a current of intracellular lymph caused by the tendency of the unsaturated colloid and the alkali molecules to add related molecules to their substance. According as the normal colloidal content or the alkaline salt content of the tissues varies from that percentage which is normal to the tissues, the function will begin to suffer, although the structure of the cell may continue to appear normal. If the alkaline salts alone deviate from the normal, we have only a functional derangement; but if the colloidal content of the tissues varies, changes in anatomic structure result—we have a pathological tissue. Accordingly, we are introduced to a conception of disease production on a physical basis, as follows: (1) Anatomical or colloid diseases; (2) functional or alkali deviation diseases. This affinity between the colloids, albumin and lecithin on the one hand, and the alkalies of potassium and sodium on the other hand, is made the basis for a new idea of tissue pathology which might make the study of the human constitution approachable on a physical basis. We know that the conductivity of any living tissue for the electric current depends upon the presence in that tissue of soluble electrolytes, this being the name assigned to the dissociated ions of salts, acids, and bases. An ion is an element set free by electrolytic dissociation. Therefore, the degree of electric resistance which a tissue normally opposes to the passage of a current is an index of the amount of ions dissociated in the water which bathes the cell protoplasm. In making this test of the resistance of tissues a great deal of preliminary work has still to be done, because the different tissues differ with regard to the degree of resistance which they offer to the electric current and they differ according to their state of rest or work. One of the first facts with which to become familiar in this study is that the greatest and highest resistance is offered by a healthy tissue and that when a tissue loses its normal resistance it has become diseased.

In recent papers found in the *Journal of General Physiology*, W. J. V. Osterhout of Harvard University has made this type of study of the mechanism of injury and the recovery of the cell a special research which he carries out on one of the common kelps of the Atlantic Coast—the laminaria (See also *Science*, April 15, 1921, p. 352).

Osterhout states that the electrical resistance of the living tissue is about ten times as great during life as it is after death, and he attributes this resistance to a layer of protoplasm surrounding the vacuole, a layer so extremely thin as to be comparable to what is commonly called the plasma-membrane.

As the passage of an electric current occurs by means of the dissolved ions in this thin layer of protoplasm around the cell substance, Osterhout concludes that the electrical resistance may be regarded as a measure of the permeability of the protoplasm to ions. The tissues have a rather constant electrical resistance. This normal electrical resistance has to be determined by proper instruments and constitutes the basis for further calculations. If an injury occurs and the resistance falls, let us say 10 per cent., we may say that the injury amounts to 10 per cent.

In the case of laminaria, if the injury caused by placing the kelp in a solution of sodium chloride amounts to 5 per cent., the tissue will recover its normal resistance if it is replaced in sea water. If, however, the injury amounts to 25 per cent., the recovery is incomplete: instead of rising to normal, it recovers to only 90 per cent. of the normal. The greater the injury, the less complete the recovery. When injury amounts to 90 per cent. no recovery is possible in this plant.

Two aspects of injury are described. One is the temporary loss of resistance, which disappears, wholly or in part, when the tissue is placed under normal conditions: this may be called temporary

injury. The other is the permanent loss of a part of the resistance which is observed after more prolonged exposure: this may be called permanent injury.

The aim of these investigations has been to apply to the study of living matter methods which have been useful in physics and chemistry. Such fundamental conceptions as vitality, recovery, and death may be investigated by quantitative methods and the investigation of fundamental processes shows that they obey the laws of chemical dynamics. It is too early to apply the results of such studies to an interpretation of such a complex physical and chemical system as the human constitution. And yet I cannot resist the belief that an ultimate understanding of the constitution of the human being will have to be based upon a knowledge of the physical and chemical processes that are continually going on in the body, and that psychological clinical and philosophical inferences which appear to be not based on biochemical studies had best be held in reserve. It is quite possible to test the resistance of almost all of the tissues of the human body to the electric current; what we lack at present are practical instruments capable of direct applications to the human tissues under various conditions, instruments sufficiently delicate, yet accurate, under the clinical conditions in which their service is needed. Electrical resistance may instruct us as to the amount of dissolved salts in the tissue juices; as to the amount of alkali; and the equilibrium between acids and bases. There certainly will be in the near future an electrolytic method of informing the clinician of the depletion of the body in carbonates and other alkali-yielding substances, for the depletion in these substances constitutes the underlying feature of the tests for acidosis, namely the change in the carbon-dioxide content: (1) Of the alveolar air; (2) of the blood; (3) the concentration of the blood in alkalies, in hydrogen and hydroxyl ions; (4) the tolerance to fixed bases; (5) the alkalinity of the blood so far as it can be determined by titration. In fact, there are such methods in existence already, but they are always associated directly or indirectly with colorimetrics in which the clinician cannot depend upon an instrument, but must depend upon the accuracy of his color vision.

Acidosis is essentially an impoverishment of the body in alkalies; this being so, it should be measurable by determining the electrolytic conductivity of the various juices that can be obtained from the living human body.

Human constitution is not based only upon the purely and exclusively chemical interchanges, or upon the purely physical changes that go on in the tissues and organs, but depends largely upon the rate of metabolism. Different men and women under normal conditions have different rates of basal metabolism. Dr. Walter M. Boothby (*Jour. A. M. A.*, January 8, 1921, p. 86) states that the normal standard of the basal metabolic rate is not exact; this is due to the fact that all the technical factors necessary to obtain a normal standard have hitherto been observed only in the studies of Atwater and Benedict, Graham Lusk, and DuBois. In fact they are not feasible as yet in the practical pursuits of the clinician. But that there must be fine differences in the basal metabolism of individuals there can be no doubt, and as Dr. G. W. McCaskey states that the Benedict apparatus is of sufficient accuracy for clinical purposes, and Dr. Henry M. Thien states the same for the Jones apparatus, there should be no difficulty in determining the normal metabolic rate in a large number of healthy human beings under strict conditions of clinical and experimental control.

For all studies of human constitution the heat phenomena inherent in the living tissues must be made expressible mathematically.

As heat production and basal metabolism are due to the processes of oxidation in the tissues, we are brought face to face with the chemical agents that intermediate oxidation and reduction in the cell, and we are at this date, thanks to the studies of Wieland, Bach, and Frederick G. Hopkins of Cambridge, England, so far advanced that we are made acquainted with the precise agent by which the cell can affect oxidation and reduction. In the Christian A. Herter lectures at the Johns Hopkins University, April 12-14, this year, Frederick G. Hopkins presented his views concerning the oxidation and reduction mechanism of living tissues. The agent which produces these chemical transformations is a substance in which glutamic acid is linked up with cystine. The amido group of glutamic acid is linked up with the carboxyl group of cystine.

Glutamic Acid CH_2
|
$CH_2 — COOH$
|
$CH\ NH_2\ COOH$

Cystine $CH_2S\ CHNH_2\ COOH$

By means of this chemical substance the cell can effect both oxidation and reduction and it denotes a very great advance in biochemistry to have lived in an age where such a great revelation of the workings of the living substance has been made.

Hitherto I have considered the study of constitution only from the standpoint of biochemistry, and this leads to a study of constitution on the basis of the functional achievement of the body. There is, however, another manner in which to study this subject, namely, the anatomical method. This has for its object exact measurements of the size, volume, and contents of the organs. These measurements will give the mathematical expression for the various anatomical apparatuses which are the physical substratum for the work which the body does.

Anatomical Investigations of the Constitution.—Exact measurements of the human body in toto and in its parts were first made by the Belgian astronomer and anthropologist Quetelet, but W. Pfitzner ("die Proportionen des erwachsenen Menschen," *Zeitschr. f. Morphologie u. Antropologie*, ii., 222) proposed certain basal figures for the various measurements, and in our own country, Winfield Scott Hall, in the *J. A. M. A.*, December 21, 1901, proposed a mathematical formula to determine the median value of human dimensions. I have personally taken up this subject in an article entitled "Anthropometric Studies of the Osseous Proportions of the Human Body, With a View to Obtaining a Mathematic Expression for Enteroptosis" (*Internat. Beiträge z. Pathologie u. Therapie der*

Ernährungsstörungen. Bd. 2, Heft 3). But it must not be forgotten that the founder of exact measurements of the dimensions of the human body is that greatest of all painters, sculptors, mathematicians, philosophers, and scientists in general—Leonardo da Vinci. ("Il Canone di Leonardo sulle Proporzioni del Corpo Umano"; Favoro Giuseppe, Atti del R. Istituto veneto di scienze, lettere ed arti, Venezia, 1917-1918, lxxvii., 2, p. 227.) See also J. C. Hemmeter, *Leonardo da Vinci as a Scientist,* in Annals of Med. History, Vol. III, No. 1, 1921.

Beneke later gave exact measurements of volume and capacity of organs of 600 cadavers, thereby making a very valuable contribution of the anatomical apparatuses which cooperate to make up human constitution.

Stiller restricted his measurements to special anatomical deviation of a limited number of organs. He thought he had found debility of muscles and nerves associated with a low position of the abdominal viscera and a tenth rib that was not attached to the costal arch, and he constructed from this a peculiar disease which he terms "morbus asthenicus." It was a broadening out of the views which Glénard had already announced concerning splanchnoptosis However meritorious the studies of Stiller may be, and they constitute a brilliant clinical advance of the state known as enteroptosis, nevertheless it must be evident that organ abnormalities do not constitute a disease until the displaced organs function irregularly. What Stiller described was not a constitution, but a disposition; it was not a disease, but rather one of the factors that predispose to a disease if certain other exogenous factors are added.

The whole subject has been gone over again by myself in an article published in the *Interstate Med. Jour.*, xix., 3, 1912. ("Splanchnoptosis, or Constitutional Neurocardiovascular Asthenia with Osseous Dystrophies and Disproportions—Enteroptosis.")

Among the anatomical deviations that may contribute to form characteristic constitutions are abnormal connective tissue developments, the thickness of the wall and the width of the aorta; endemic goiter; and the so-called status thymicolymphaticus. All of these conditions are found only as narrowly circumscribed or restricted organ abnormalities and they are not in themselves sufficient to make up a constitution. Above all things, it is necessary to insist on a definition of what a constitution is in a normal creature. (See definition previously given.) The great problem of research concerning the human constitution must be to define at least part of its entity in mathematical terms.

In all measurements of the type quoted in the preceding, we can deal only with the supporting tissues and structures—the bones and connecting tissues, and it must be evident that from such canons of human proportions, we can obtain only mechanical conceptions concerning the totality of the human machinery. When we get to other tissues, for instance, the central nervous organs, and the glandular organs, we become convinced that it is not structure and form, but the achievement and the work done by the organs which is of greatest importance in the question of constitution.

Functional Investigations of the Constitution.—Every expression of life of the organism is bound to its basic elements, the cells; but deviation of function, either depressed or exalted, can occur without any demonstrable change in the anatomic structure of the cells, and for the practical clinician function is more important than structure, for as all endeavors of therapy must be directed toward the restoration and maintenance of function, it is essential to know what a diseased lung, liver or spinal cord may still be able to accomplish rather than to ascertain how these organs appear under the microscope. This has led to the great development of functional tests which have revealed the fact that conditions of insufficiency of the kidneys, the heart, the liver, and so on, may exist without any morbid state becoming manifest. Such latent or potential organ insufficiencies are discovered in the entire absence of symptoms, and they constitute partial factors of constitution.

The clinical investigator on discovering such secret defects in an apparently healthy body, naturally becomes elated over the penetrating power of instrumental and chemical research, a state of elation that rapidly calms down when he asks himself the question—"What is the cause of these potential organ insufficiencies?"—for certainly we have the secret of the constitution not plainly before us by merely establishing a latent or potential organ insufficiency—we must still find out what produced this.

In an address to the American Therapeutic Society in Washington by invitation of the Program Committee of 1913 on "Hypertonicity and Hypotonicity of the Vagus and Sympathetic Nervous Systems" I called attention to certain neurochemical synergisms of the normal body and the pharmacodynamics of certain exogenous and endogenous chemical substances. The address was published in the *N. Y. Med. Jour.*, January 17, 1914. A part of the article deals with the question whether or not disturbances of the endocrine system can be recognized before they have led to distinct disturbances in the organisms. At that date the investigations of Eppinger and Hess, and of H. H. Meyer, concerning the provocative introduction of adrenalin and certain pharmacal substances had already been undertaken, and they revealed a definite reactability, that is, a readiness to respond to these chemical substances in certain systems of nerves, especially the autonomic and sympathetic systems.

The entire inspiration to this field of research is due to Brown-Sequard, and the coordination of countless physiological discoveries and anatomical research with the objective facts elicited from clinical investigation has been illuminated by no one in such a talented manner as by our fellow member, Sajous. One has only to read and study his chapters on the Internal Secretions in Their Relations to Pharmacodynamics to be impressed with the truth that here is a new revelation of therapeutics, not new in the sense that nobody ever announced such ideas before him, but new in the clinical sense that at last the dawn of a new therapy has broken, a therapy that is at once rational and practical.

The labor of this brilliant coordination of the facts of science with the demands of practice could only have been accomplished by an encyclopedic mind. But also concerning the nature of human

constitution, the study of the endocrine system throws a brilliant light. It is established that the anemia of young females at a certain age is not as Virchow thought, due to congenital narrowness of the aorta, but to defective function of certain blastogenic glands and of the bone marrow. There is an endogenous obesity which is independent of the amount of food taken in. This obesity can continue even when the food is reduced below the caloric requirements; for it is due to certain disturbances of the thyroid gland and the pituitary body. We know that diabetes is associated with the internal secretion of the pancreas.

There are revolutionizing dystrophies of the entire human frame which change, as it were, the tribal appearance of the human being—mongoloidism, eunuchoidism, infantilism—which are due to a disturbance in a reciprocal balancing of various endocrine systems and the status thymolymphaticus is only intelligible if it is viewed in the perspective of disturbed internal secretion working on the total organism.

That vast field of research on immunity which has been blasted out of the unknown by Metchnikoff and Ehrlich, which is based upon the explanation of the formation of antibodies, etc., as well as the defensive ferments of Abderhalden, are human endeavors aiming not only at the cure and prevention of disease, but unconsciously laying bare some of the secrets of human constitution; for antibodies and defensive ferments are products of body cells.

When we ascertain by analysis of blood that certain specific immune bodies are circulating in the body we gain a profound insight into the economy of the organism and, to some extent, into its disturbances. But the entire constitution and the entity of the disease afflicting it is even then not open to our eyes; for most of the factors that go to make up the human constitution are not acquired by the individual during life, but the greatest part of these factors is inherited. The factors of inheritance, as well as of acquired constitution, lead us to a brief consideration of heredity.

Constitutional Immunity Due to Selective Adaptation Between the Human Being and the Infecting Organism.—Prof. Max Neuburger, in his historic studies of the epidemics of antiquity, has emphasized the impossibility of ascertaining in our time what the exact diagnosis of those diseases may have been. In very remote periods, for instance, in the plagues described in the Old Testament, (II. Samuel, xxiv., 15, 16; I. Chronicles, xxi., 14-16; in this epidemic 70,000 people lost their lives; Numbers, xvi., 49, the epidemic of Korah, in which 14,700 people died) a diagnosis in our sense of the word was not attempted, in fact, was impossible. Such a master of historiography as Thucydides has described a destructive infectious disease which invaded Athens during the Peloponnesian war and given a minute and detailed account of the epidemic; and yet no clinician of the present day is able to state what disease this was, and Iwan Bloch maintained that the venereal plagues mentioned in the Bible (Baal, Peor) are not the same as present-day lues, etc.

The truth is that in the course of thousands of years reaction between the cause, by which I mean the peculiar constitution and disposition, and the releasing factor, the microorganism, may change so fundamentally that their outward phenomenon called the disease is no longer recognizable by the posterity two or more thousand years remote and does not fit into any of their classifications. There may have been many diseases in prehistoric times of which we have no record whatever, and there may have been others which thousands of years ago presented pathogenetic manifestations which to-day cannot be forced into our schemes of clinical classification.

But there is still another factor in the ceaseless adaptation between the human constitution and pathogenetic factors, and this I have called the reciprocal selective adaptation between the human constitution and certain infective organisms.

It is well known that the bacteria of different types lose their virulence and power to form toxins readily. It is also known that these two properties can be increased when a certain strain of bacteria undergoes what is known as animal passage, that is, the microorganism is made to exist for a time in the bodies of one or other of the mammalia.

In artificial culture microorganisms rapidly lose their virulence. It is also known that the virulence against one species of animal is as a rule specific and that virulence specific against one type of animal may go hand in hand with diminution of virulence against another type. Martius, in his "Pathogenese innerer Krankheiten" (1909), gives the evidence that pathogenicity is not a constant property characteristic of bacteria, as for instance, proteolysis is characteristic of certain enzymes, like pepsin or trypsin, but rather that pathogenicity signifies the ability of the bacteria to react in a specific manner when they come into a medium corresponding to their biologic requirements. Now this is nothing but a functional adaptation to certain chemical and physical conditions which the life of the bacteria require. The bacteria, in fact, have their constitutions and dispositions also, just like human beings.

In the following I will endeavor to make clear that infectious diseases that may have existed during former historic periods of the human race may have disappeared entirely, because the reciprocal relation between the constitution of the human and the constitution of the bacteria have been so adapted reciprocally that instead of a disease a form of symbiosis (living together innocuously) has been established.

Let us take the instance of one single infective organism—the bacillus of typhoid fever. It is well known that this organism, when existing in nature, loses its power of multiplication, eventually dies and disappears; on the other hand, by continued animal passage, or change of the host in which it then forms what the clinician calls an infection, its power of multiplication can be indefinitely increased.

Now it happens that the temperature and the chemical composition of the human body coincide with the conditions of the most prolific growth and most intense effectiveness of all the vital functions of these bacteria. In other words, the human body presents the optimum physical and chemical conditions for the growth of the typhoid bacilli, and but for the human body this bacillus and a large number of other pathogenic bacteria would be doomed to

extinction. In comparing the colon bacillus with the typhoid bacillus, it is found that the *Bacillus coli* can live without the human body, and by many bacteriologists is considered ubiquitous.

The next step in the development of the symbiosis is the phenomenon of the so-called human bacillus carriers. It is known that human beings can carry pathogenetic germs in their bodies for many years without being sick themselves. There are two classes of carriers: (1) Those who have already gone through the specific chain of pathological events, called in this case typhoid fever; and (2) those who have never had typhoid fever and yet show typhoid bacilli in their stools. In both instances the bacilli live in the optimum condition.

Dr. L. Radcliffe Grote of Halle does not consider that this carrying of bacilli is an accidental collateral phenomenon of the disease caused by fortuitous immunity processes in specific individuals; but he conceives it as the end result of a long series of processes culminating in a reciprocal adaptation between the infecting organisms and the host. Both factors have eventually reached a form of coexistence which corresponds to the biological conception of symbiosis.

The conception of symbiosis demands that the coexistence of two different kinds of organisms shall result to the advantage of both. The bacilli of the coli group offer to the human being a very distinct and important advantage because the glands of the digestive tract secrete no ferment which can digest cellulose. The splitting up of the capsules of most leguminous vegetables can be accomplished only by the intestinal bacteria, and in the experiments of Schottelius it was found that hens and goats which were kept under absolutely aseptic and sterile conditions of life did not grow as well as animals of the same strain who were permitted to fill their intestinal tract with bacteria.

Not all human beings are fitted to develop a state of symbiosis with certain bacteria, and not all bacteria have the properties fitting them to mutual adaptation with the human host. Specific and peculiar constitutions in both the host and the microorganism are necessary.

This process of mutual adaptation no doubt is one of the phenomena of natural selection and may have been going on between our race and parasitic infective agents for millenniums. Diseases which may have once wiped out human beings by the hundred thousands to-day do no longer exist (Psalm xc., 3) and infectious diseases of a severe type to-day may be unknown to the clinical historiographer of the year 3000. "*A disease*, accordingly, *is a phenomenon of collision between the biologic requirements of an infective organism and the human constitution organism in their effort to reach symbiosis.*" The vital necessity of both organisms conflicts in this struggle and the disease process is the expression of a process of adaptation between the host and the parasite. (L. R. Grote, *Münch. med. Woch.*, 1920, 38.) According to a footnote in this article Prof. von Drigalski made the observation in epidemiological investigation before 1904 that the typhoid bacillus can displace the colon bacillus completely and fill its biologic rôle in our body. He studied persons who permanently excreted pure cultures of the typhoid bacillus in their stools. These observations cannot be interpreted in any other way than that the typhoid bacillus has assumed the total work of the intestinal flora in man, and this means a most extensive adaptation of the typhoid bacillus to the requisites of the human intestine. Thus in this intensely interesting form of adaptation and natural selection both the human host, as well as the bacteria, undergo very grave fundamental transformation. The evident antagonism between both organisms during the disease has to be transformed into a reciprocal adaptation requisite to symbiosis. For both factors, host and parasite, the destructive element of the disease represents a very dangerous stage of transition. The human organism meets and equalizes the exigencies of this dangerous transition by the requirement of immunity. The bacteria meet them by colossal celerity and power of multiplication. Some bacteria develop so-called resisting permanent or enduring types.

I have gone into this phenomenon of symbiosis between host and parasite because it is not considered as one of the elements of the human constitution, and still it must be evident that it is a process which is continually going on almost unconscious to the clinical observer.

Heredity.—The properties or peculiarities which an adult organism capable of progeny possesses may be divided into three groups, according to their derivation: (1) The great majority of all properties of an organism were already possessed by his ancestors; these are the inherited properties. (2) There are properties by which an organism, it is true, differs from its ancestors and therefore are not inherited; yet he possesses them from the date of his birth onward; these are the congenital properties. (3) Every organism shows properties which he does not acquire until after his birth during the course of his individual life; these are the acquired properties.

The hereditary and congenital properties are conditioned by peculiarities of the blastogenic cells. They are therefore termed *blastogenic*. The acquired properties at the present time are considered as independent of the germ-plasm. They are pure acquisitions of the *soma* and, therefore, defined and distinguished as *somatogenic* properties.

If the differences between descendants and ancestors are very slight, and if, in addition, the differences between various individuals of the same brood among themselves and with the parents are connected by transitions, so that they can be brought in a continuous series, then we speak of *fluctuations* or *continuous variability*; but when these differences between the parents and descendants are very great, and also if the brood can be separated into two sharply distinguishable groups which cannot be arranged in a continuous series, then we speak of *mutations*.

To-day one often meets with the conception that only the mutations are inheritable, and not the fluctuations. This is due to the fact that the mutations are strikingly different from the original stock and therefore are more easily detected.

Thus far it has not been satisfactorily demonstrated that somatogenic properties are really inherited. The experiments of Standfusz, E. Fischer, Sumner and Kammerer seem to prove the trans-

mission of somatogenic properties, but Tower found that in repeating some of his experiments, that the influence of the experimental changes on the blastogenic cells could not be excluded. Almost all these observers, it was later on proven, had practised an unconscious natural selection, and Jennings concludes that the problem of the hereditary transmission of acquired characteristics in the infusoria meets with the same difficulties in the protozoa as in the metazoa.

As heredity plays such an important part in the transmission of human diseases, it must be evident that this subject cannot be considered as finally closed until it can throw light on human pathology, which long experience has demonstrated in certain definite forms to be transmissible.

The modern conceptions concerning the proliferation of the maternal and paternal blastogenic cells explain the process in such a way that the cells that serve future generations early separate from those cells which are to form the rest of the body; in other words, the blastogenic cells slumber in the germ glands until maturity of the individual, and thus the idea of continuity of blastogenic germ plasm brings with it the other idea that the entire body, all organs including the brain and their activities, are merely appendages for the preservation of the blastogenic cells which decide the species.

Degeneration of the body constitution acquired during life may affect the germ plasm, but hardly in a specific form of change of its inherent qualities so that the identical constitutional abnormality acquired by the parents shall be in evidence in the descendant. Such an influence has been termed parallel induction of the somatogenic and blastogenic cells.

In my article (*loc. cit.*) on the anthropometric measurements, with a view to establishing a mathematical expression for enteroptosis, I expressed the opinion that a frequently or continually repeated parallel induction of body and blastogenic cells might affect the chromosomes and plasma of the latter by summation of the stimuli. I mean that eventually a specific change may be produced in the blastogenic cells, although this may not be evident in the first or second generation. A conception like this meets with great difficulties unless an exceedingly intimate chemical connection between the somatogenic and blastogenic cells is conceded. That such a connection exists can be no doubt, for all the gonads, in addition to their external function, have also an internal function as endocrine glands. This explains the fundamental changes of the entire body during the development of maturity and the peculiar disturbances of the constitution in eunuchoidism and allied states; and conversely there is a dwarfed and defective function of the gonads when the pituitary body is diseased. The functions of the entire organism consists of a complex reciprocal correlation of the organs themselves, and there is possible, also, a functional adaptation of the growing, and yet undifferentiated cells to new external conditions of life.

If this adaptation concerns organs that stand in a close altruistic relation to the blastogenic cells, then it is conceivable that during the course of long periods of time, when these influences are effective in the same manner through generations, new inheritable properties can be acquired. The Darwinian theory of natural selection conditions a far-reaching variability of the blastogenic cells, and if some biologists assert that natural selection is the only way of evolution, then this power of variability in the germ cells must be infinitely great and must have been present already in the very beginning of organized matter. Plate asserts, therefore, in view of the insufficiency of these conceptions, that the principle of the hereditary transmission of acquired characteristics is a logical demand upon the thought of future investigators.

Overculture and Race Degeneration.—When the deleterious changes of the constitution are not confined to individuals, but extend to entire races or people, they can only be explained by influences which have worked upon long series of progenitors in the same manner. Such changes are noticeable among our race at present, and to convince the casual reader of this I will merely mention a few that will spring into the attention of anyone who cares to undertake the observation: (1) The increase in the inability of young mothers to nurse their children; (2) the increase in dental caries; (3) the increase in the number of individuals under thirty who have an impaired vision; (4) increase in otosclerosis; (5) the increase of rachitis; (6) the increase in the digestive disturbances and faulty nutrition; (7) the increase in psychic instability (psychasthenia, neurasthenia).

The race is losing part of its aboriginal instincts whereby the adaptation and reaction to environment was entirely automatic and sub-conscious. The race has become so accustomed to an extensive protection against all dangers to our existence that it has come to an insufficient use of our locomotor apparatus—nerves, muscles and bones. In addition, the modern means of transportation and the intense strain upon the central nervous system, created by the close cohabitation in colossal modern cities, leads to rapid exhaustion of these noble master organs. All the achievements of culture by the progress of hygiene, artificial immunity, sanitation, physiologic dietetics, operative technique, cannot compensate the race for the colossal loss of automatic sub-conscious adaptation of our organism to nature, if this should continue.

All these advances that I have mentioned cannot restore this biocosmic reciprocal automatism between man and nature. The aim must be to induce the race to get back to nature; a colossal and almost impossible task when one reflects that it means the dissolution of the big cities; the restoration of human beings to a life in the country, or at least in so much country that each individual is assured the requisite amount of natural earth, air, sunlight and immunity from the contamination of great cities.

Mendelian Theory of Inheritance.—In 1865, Johann Gregor Mendel published under the title, "Versuche über Pflanzenhybriden," in the Proceedings of the Society of Natural History of Brünn, Austria, his law of heredity. He made prolonged experiments in crossing varieties of the pea (*Pisum sativum*). His paper was overlooked until attention to his remarkable results was called by De-

Vries in 1900; he and also Correns and Tschermak at the same time independently rediscovered Mendel's law. Mendel selected seven pairs of characters, such as the shape of the ripe seed, of the cotyledons, of the seed-pod, color of the seed-skin, length of stem, etc. Large numbers of crosses were made between peas differing in respect of one of each of these pairs of characters. It was found, says Bateson, that in each case the *offspring of the cross exhibits the character of one of the parents in almost undiminished intensity*, and intermediates which could not be at once referred to one or other of the parental forms were not found. "*In the case of each pair of characters there is thus one which in the first cross prevails to the exclusion of the other.*" This prevailing character Mendel called the dominant character, and to the other he gave the name of recessive character.

Every Mendelian element in the germ plasm is represented by one or more inheritance units which are called *factors* or *genes*. Weismann and DeVries assume them to be living particles, and other theoreticians in inheritance assume them to be enzymes. Continued amphimixis of brother and sister in the human race has not occurred, and therefore, in our race, we have hitherto only accidental resemblances to Mendel's law. Marriage among close blood relatives may have been a racial necessity in the very earliest prehistoric state of the human race. The Mendelian idea that a descendant always has a definite calculable part of the heredity mass of his ancestors, but not a molecule of strange germ plasm, is with the human being an impossible conception.

Galton, on the basis of an investigation of heredity in certain animals, has formulated his results to the effect that, in a given case, 0.5 of the inborn characteristics will be derived from the two parents (0.25 from each), 0.25 from the grandparents collectively (0.0625 from each), 0.125 from the great-grandparents taken together (0.015625 from each), and so on in similarly diminishing proportion. This law, further elaborated by Pearson, and in some slight degree corrected on abstruse mathematical grounds, is by him acclaimed as a scientific generalisation of immense importance, comparable for its power of resuming in one brief statement innumerable facts, to Newton's famous law of gravitation. Apparently, on this hypothesis, the inborn qualities of an individual will be fully covered by the sum of inherited qualities (S—1) only when the lineage has been carried back *ad infinitum*. Go back only a few, say ten, generations, and you have already reached the source of the great majority—some nine hundred and ninety-eight out of each thousand—of inherited characteristics. (Chas J. White in *Makers of Men.*) But go back as many generations as you like, and a residue, albeit infinitesimal, of inborn qualities, not yet accounted for, will confront you still. And in dealing with human individuality, it is to be noted that some quite inconspicuous but deep-seated quality, of remote and obscure origin, may quite well be, in any given case, the little leaven that leavens the whole lump. Hence, in part, the apparently paradoxical results often attained by consideration of the recent family history of remarkable personalities. Beyond all available human records, beyond all human ancestry, beyond the prehuman mammalian and submammalian stock, beyond the primeval monocellular starting point, even to the groundwork of inorganic nature, we must pass for our ideal completion of the sum of inborn mental and physical characteristics. There the manifestation of the contemporary human career has its dawn; there the *Ego* begins its æonic march towards the fulness of predestined activity. (White.) It is further to be noted, with reference to Galton's law, that it is a statement of averages only, for "the introduction of the Mendelian law, combined with the results of recent cytology," makes it likely that in any given individual the maternal and paternal factors lie side by side and separate out in the gametes (ova or spermatozoa) of that individual, so that we do not inherit equally from all grandparents of each generation, but all from some and nothing from others.

739 UNIVERSITY PARKWAY.

THE ARREST AND CURE OF DEMENTIA PRÆCOX.

BY BAYARD HOLMES, B.S., M.D.,

CHICAGO.

THE opinion prevails that dementia præcox is irrecoverable. A careful reading of the literature discloses the fact that an occasional case with indubitable symptoms of this disease spontaneously recovers after decades of deteriorating custody, and after symptoms, too, indicative of the most pronounced cerebral affection. The recoveries are, moreover, marvelously complete.

On the other hand, the histopathologic records of Ranaudie and the investigations of Southard, Gurd, Rawlings, Sir F. W. Mott, and Monokow and Kitabayashi demonstrate actual destructive lesions which give adequate pathology for the unfavorable or absolutely grave prognosis attributed by alienists to this disease.

There is, however, one fact common to all these pathologic studies which must not be overlooked. Each of these students of the histopathology of the brain remarks the pregnant observation that the extent of the histopathology of the cortex and of the choroid is not uniformly proportionate to the gravity or duration of the mental symptoms. While the lesions are easily coordinated with the character of the symptoms when the lesions do exist, they are not always demonstrable. Some patients give a history of grave and prolonged symptoms without recognizable destructive cerebral lesions.

If one will accept for the moment my own theory of the production of this condition, the occasional phenomenon of a complete recovery after the gravest manifestations of the disease exhibited over a period of decades even, will not be incredible or inexplicable. According to this theory the disease is an intoxication. The toxin is produced in the cecum. The factors in its production are remnants of the patients' food, colon bacilli, time, temperature, hydrogen ion concentration and fluidity.

At the present time the food factor is presumed to be the aminoacid histidine, or a histidine like polypeptid.

The potent colon bacillus may or may not be a

special stirp. Our researches do not suggest more than the probability of specificity.

The time is measured by the retention of the cecal contents in a liquid condition in the active muscular cecum, on the one hand, and, on the other hand, by the time required by the particular strain or stirp of the colon bacillus to decarboxolate or catabolize the iminazol containing polypeptid, or the histidine.

The temperature is limited to the body temperature in health. Clinically, dementia præcox patients have shown improvement during pyrexia, especially during typhoid fever. This betterment in the symptoms might be due to the existence of a temperature unfavorable to the pathogenic stirp of the colon bacillus.

Each stirp of the colon bacillus has decided idiosyncrasies of growth in which the hydrogen ion reaction is a conspicuous factor. The contents of the ileum are alkaline from the duodenum to the ileocecal valve. The contents of the cecum have been found to be variously neutral and acid. Hp = 5.2 — 62. Under differing conditions of Hp the rapidity of growth of a specific strain of the colon bacillus varies and hence the amount of toxic residue of an aminoacid or polypetid food would be increased or diminished by changes in the reaction.

Microorganisms, and especially the colon bacilli, grow most rapidly, other things being equal, in a moving liquid medium. The contents of the cecum are a liquid mixture to which the residue of the ileum is added in little liquid squirts through the ileocecal valve. The regular and often powerful antiperistalsis of the cecum insures a thorough mixing, thus promoting the bacterial growth. At the hepatic flexure, there is a loop of the transverse colon two or three inches long, in front of the ring of Cannon, which ring is conspicuous in our patients. The wall of the cecum is more muscular than normal as a result of a sort of compensatory hypertrophy to overcome spasmodic constriction of the ring of Cannon. The cecal mucosa is essentially an active absorbing surface, while the mucosæ of the transverse and descending colon are only indifferently absorptive.

Our theory places the production of a toxic molecule in the cecum, which molecule, by a selective process, acts upon the brain to produce the mental symptoms and later the histopathologic lesions of dementia præcox. These symptoms are at first produced by a simple cell intoxication, which poisoning may, and does in some patients, go on to the destruction of the brain cells, as witness the figures and descriptions of the histopathologists. The symptoms which are first noticed in the majority of cases of dementia præcox are suggestive of cerebral irritation, but a careful inquisition generally develops evidence of an antecedent period of depression or habitude.

The sexual excitement of dementia præcox patients is of uncertain genesis. Ceni has shown conclusively that the molecules of cerebral neuroglia are toxic to the spermatogenesis of the testicle when liberated by cerebral concussion in animals. It seems highly probable that the genital symptoms of dementia præcox are secondary to the destruction of cerebral cells and the liberation of cerebral molecules. In any case the testicles and the ovaries of dementia præcox patients become smaller as the disease progresses, and the testicles are devoid of living spermatozoa in the majority of dementia præcox boys.

With such a theory of the disease, and after the demonstration of a cecal stasis of three days or more, it has seemed to me reasonable to attempt to terminate the production of the toxic amine by daily irrigations of the cecum with large quantities of water, five hours after the last meal of the day.

After demonstrating the inefficiency of enemas and discovering the existence and potency of the ring of Cannon, I was compelled to attempt the daily cleansing of the cecum through an appendicostomy.

Clinical demonstration is not popular to-day. This is the age of the laboratory method. Nevertheless, the clinical method is a most scientific and practical method. Its results may be demonstrated *ad libitum*. Especially is this the case with our theory of dementia præcox. No concourse of accurate laboratory experiments can equal in power of conviction a single clinical experiment which any general practitioner of medicine may institute and follow out with his next case of dementia præcox. It is for such general medical men as still have confidence in the value of clinical evidence that this presentation is made.

Let my theory of the origin of dementia præcox be accepted provisionally by the unprejudiced physician, and the indications for treatment would be immediate appendicostomy and daily irrigation of the cecum through the colon until all amino-acids are removed.

Case 1.—The first patient on whom this procedure was undertaken by me was A. H., Chicago. He was born of a good family, and brought up and educated by his mother's sister, a maiden lady of means, who was very fond of him. His physical development was superb, and he presented an artistic temperament, drew well, wrote in an original manner, and read metaphysical and philosophic literature extensively. He had a desultory education, about equal to a high school course. He was a smart dresser, and was convivial in disposition.

In June, 1914, he had given no suggestion of impending breakdown, so far as his aunt can recall, when suddenly he disappeared on his way by train between Philadelphia and Atlantic City. On leaving Philadelphia he had a small sum of money, not more than $12, and was well and appropriately dressed. When found in the swamps of New Jersey, two weeks later, he was practically a naked, emaciated, confused, incoherent, drivelling dement, refusing food and screaming, crying, and refusing every attention. He was taken to a hospital for a short time and nursed back to relative physical health. Several alienists saw him and made the diagnosis dementia præcox, recommending custodial care.

The parents in Chicago decided to take him home, and did so in 1915. At home he was seen by several consultants, who confirmed the diagnosis. He made some improvement, but remained untidy. The dementia præcox attitude increased, with verbigeration, mannerisms, peculiar drawings and impulsive laughter. He continued below weight, though able to feed himself when brought to the table. He slept in a semicatatonic supine position, his head elevated above the pillow. He could not be made to keep his bed dry and clean.

In July, 1916 his father consented to have appendicostomy performed, and the boy was taken to the Lakeside Hospital, Chicago. After careful catharsis and enemas, the appendicostomy was made and the colon irrigated with three quarts of dilute magnesium sulphate solution, while the patient was still on the

operating table. The patient was placed in a private room on the first floor under the floor nurse.

Early the morning after the operation the hospital clerk telephoned me that my patient had escaped from the hospital. He had dressed himself, taken his small hand bag and disappeared. His father informed the police, but within two hours he arrived home, having spent 10 cents for street-car fare out of 40 cents left him.

During the following six months his father irrigated the colon through the appendix with water, in which a small amount of magnesium sulphate was dissolved. The patient sat on the stool in the bath room. The ten-quart pail was hung about five feet above the stool and connected by an ordinary rubber tube with a dull glass point to the appendix. When the irrigation was begun the father read aloud to his son, thus passing the time profitably.

The patient improved rapidly and became tidy and dressed himself, came regularly to his meals, went out alone on the street, visited the movies alone, and began to write coherently and make drawings of real merit. He conversed with the family, and conducted himself properly on the street. He assisted some about the house. His father took him to a commercial art school, where he did some very interesting drawing.

At the end of a year the patient was much better than before the treatment was begun, but he could not assist his father in the office. He was particularly deficient in figures and unable to copy addresses from printed lists where some selection was necessary. On account of family conditions and social prejudices it was not possible for me to study the patient with any care or thoroughness. From the most cursory tests he seemed to be feeble minded or partially demented, though his mental condition before his episode is not well attested.

His improvement after appendicostomy was prompt and has been permanent more than four years, but there remains pronounced mental defect. We are uncertain as to the origin of this defect. He might have been originally feeble minded. Against this presumption is the fact that he has none of those habits and tendencies which are so common among the moron group. The history is against it also.

The patient had but one acute episode of little more than two weeks' duration, during which cerebral changes could have taken place. If considerable patches of neuroglia were destroyed, the destruction must have been rapid.

CASE II.—The second case contrasts with the first in many respects. A. B. was the third of four boys. His next older brother died of appendicitis when 13 years of age. His younger brother and the oldest are both alive and well. His paternal ancestors are all very long lived, and of Scotch-Canadian origin. His maternal ancestors are old New England stock, without any hereditary taint. In 1913 A. B. was 18 years old, and in the second year of high school. He was working outside of school delivering papers when the first acute episode came on suddenly. There was no doubt of the diagnosis of dementia præcox, and he was sent to a private sanitarium in Wisconsin. He required restraint. At the end of nine months he returned home.

During the following seven years he had several episodes of much the same severe catatonic character, and was placed in several different private institutions. His symptoms were accompanied by great loss of weight, and he was generally mute and untidy for two or three months at least on each occasion. The gravest prognosis was made at each institution in which he was placed. In the autumn of 1918 his last and most protracted relapse began. He was taken to the summer home of the family in Florida, and his mother and a helpful woman of mature age and some experience took care of him. His condition grew worse and worse until March, 1919, when he was taken to a sanitarium at Orlando, Fla. He was tube fed at once, but continued to lose weight, and bed sores appeared over sacrum elbows and knees. His weight fell to 74 pounds.

At that time his family decided to have appendicostomy performed, and under my written direction Dr. Clyde Brady performed the operation in Orlando on Aug. 1, 1919. Irrigation of the cecum and colon was begun ten days later. Since that time A. B. has made continuous improvement. In May, 1920, he returned to Chicago with his family, at which time he could walk. He celebrated his twenty-fourth birthday in August, 1920, with a little dancing party at his father's house. In January, 1921, he returned to Florida with his family. It was my privilege to visit at the family country house on one of the inland lakes and see for myself what his physical and mental condition had become.

The young man was alert and smiling as we drove up to the house, and helpfully and cheerfully welcomed us, for my wife was with me. It was supper time, and he assisted his mother and grandmother in getting the meal on the table, during all of which time he took part in the conversation in a most animated and vivacious manner.

On the following day I assisted him in finishing up the front door steps or entrance. It had been found necessary to replace the original steps. A. B. had planned these new steps himself. They were eight feet wide, and made of two-inch yellow pine on a broad cement foundation. The plan was rational, original, and yet architecturally in the vernacular of the new South. It was consistent with the house, for which it was the introduction. I worked with him in making the lattice work, and he talked and joked in a very natural and cheerful manner. He recited for me the 100th Psalm, which he said he had learned in his first year at high school, and did it without an error and with little hesitation. This was the first time he had recalled it in years. A day or two later he recited Hamlet's Soliloquy without break or hesitation until he came to "conscience makes . . ."; there he halted for a moment and, after slowly recalling the word, went on without further assistance. He drove the automobile part of the way coming home from Daytona, and took care of the car every morning before it was used. He always caught the minnows for bait without suggestion or jogging, and took me or any other guest out fishing with all the proverbial graciousness of the Southern host. He helped about the house and did errands in town for the family.

His memory of the happening during his worst condition is remarkable and apparently objectively complete. While at Daytona we occupied the same room in the hotel. He described to me his first sanitarium experience. He said the nurses locked him into a room and neglected him. They refused to give him a glass of Epsom salts which had been ordered, and he reported it to the doctor when he came around. The doctor, whose name he recalled, told him he was making too much trouble for $25 a week, and ordered him sent to a back ward with old paralytics, and there he was locked in a room, and at last tied hand and foot for nine days to his wet, stinking bed. His bowels didn't move until the ninth day, and then in bed. He spoke of such conditions with appropriate disgust.

He wrote a four-page letter to his father immediately on receiving a letter from him, and did it quickly and with extreme neatness. I read the letter, which was direct, brief and consequential, and found not a single error in spelling, punctuation or syntax. It was excellent in every particular.

A. B. has suffered a continuous but mild pyœphrosis since he returned from Florida in May, 1919, and Dr. Louis Schmidt of Chicago catheterized both ureters and reported both kidneys infected with colon bacilli only. The pus still shows itself. He also has some chronic posterior nasal catarrh, and a disagreeable hawking mannerism.

On first returning to Chicago from Florida in May, 1920, his head was thrown forward on his shoulders in the manner peculiar to catatonic dementia præcox, but he has straightened himself up, without any formal gymnastic training, until this deformity cannot be noticed. His voice has returned to nearly normal from the roughness and uncertainty which it showed at first.

His mental tempo was not noticeably slow, but his physical expression of mental phenomena was retarded and is more like that of an old person than of a boy. In working on the porch he was careful not to waste lumber and used short pieces economically. He was slower in deciding which pieces to use than a youth

usually is. In fishing he was less impetuous than most young men, and more patient when he got a strike. His memory of dates and places in the past was good, and he knew where everything was in the house as well as the average boy, but he did forget an errand now and then among the multitude of things necessary to get when going to town. There are a great many things to do on a country place in Florida, and he seemed to be able to keep the place in order and attend to many matters in the house.

Every day he irrigated his cecum with ten quarts or more of warm water, to which he added some growing yeast in sweetened water. This usually took at least three-quarters of an hour. Several times he had tried to drop the irrigation for a while, but he recognized that he could not neglect it.

If any one incidentally met A. B. he would notice no abnormality, but only a deliberation not quite consistent with his age.

Since returning to Chicago in April, 1921, he has had a febrile attack which led to an *x*-ray examination and the demonstration of calculi in both kidneys.

Comparing these cases, one is surprised that the single short episode of Case I was attended by more permanent mental enfeeblement than the repeated, prolonged severe episodes of Case II. Then treatment was begun within three years of the first symptoms in Case I, and improvement was quick and sharp, but not complete, while in Case II treatment was not begun until after six years, and it was slow, steady, and seems to be miraculously complete.

One would naturally expect better results from appendecal irrigation in cases of recent onset, and would be tempted to give a grave prognosis in the prolonged disease and in cases where there had been many severe episodes. Some evidence outside these two cases leads me to doubt the dominance of either time or severity of symptoms in making an unfavorable or favorable prognosis after treatment.

The indications for treatment, then, should not be fixed by the duration of the disease. Until investigation and research have furnished data to explain the miraculous phenomena of recovery after appendicostomy and irrigation, and some objective means of measuring the intracranial destruction *intra vitam*, we must go on and offer the severest and the oldest dementia præcox patients the hope which clinical history and this therapy suggest.

30 North Michigan Avenue.

PSYCHOGENIC AND NEUROGENIC FACTORS IN SKIN DISEASES.*

By MOSES SCHOLTZ, M.D.,

Los Angeles, Cal.

Dermatologist of the Graves Dispensary, Los Angeles Postgraduate Medical Department, University of California, Los Angeles County and Kaspare Cohn Hospitals.

THAT the nervous system plays an important part in the etiology and pathogenesis of skin diseases has been vaguely felt and empirically established long ago. With the extension of medical research a number of clinical observations have been accumulated to demonstrate such relationship. However, both neurologists and dermatologists have cited the facts and observations from their respective points of view only, in a casual and detached manner, without classifying the data or attempting a comprehensive analysis of them. To attempt such an analysis and to offer a systematic presentation of the known clinical facts of interrelationship between the nervous system and skin diseases is the purpose of this paper.

Psychogenic Factors.—The conventional division of neurogenic factors in psychogenic and neurogenic proper, *i.e.* sensorimotor and vegetative neurogenic, is maintained also here for the reasons of practical convenience.

Psychogenic factors play in the pathogenesis of skin diseases a much smaller part than vegetative neurogenic; yet the frequency of their clinical incidence is sufficient to merit a closer study and attention. A psychopathic condition most commonly met with in skin diseases is *mental depression and hypochondria* developing in chronic distressing itching or disfiguring dermatoses. This depression is often so deep and unbearable that attempts at suicide are not a rarity in these cases.

There is one dermatologic condition due directly to the mental morbidity and instability—this is *dermatitis factitia* in hysterical subjects. Dermatologically lesions of dermatitis factitia betray themselves by sharply defined borders, by unnaturally regular and fantastic shape and, above everything else, by being limited strictly to the parts of the body within the reach of the patient's hands. Therapeutically, lesions of dermatitis factitia are entirely within the neurologic sphere, offering a fertile field for psychoanalysis.

A clinical form standing morphologically very close to dermatitis factitia is presented by *neurotic excoriations* frequently observed in neurotic individuals. This form differs from dermatitis factitia mainly in the pathogenesis. In dermatitis factitia the lesions are produced deliberately for various purposes of a personal nature. Neurotic excoriations are self-inflicted involuntarily and subconsciously, as the result of a neurotic disposition and restlessness.

The incidence of skin lesions in various psychoses and their possible pathogenetic relationship is only casually recorded and hardly at all studied. This enormous field of research has been sadly neglected. Only scant and scattered observations are available on the subject. Thus Church and Peterson[1] record the following anomalies of the skin in various forms of insanity: Adipose thickening, polysarcia, precocious and abnormal development of the hair, premature grayness, hypertrichosis, vitiligo, pigmentation, nevi, adenoma sebaceum, molluscum fibrosum, ichthyosis, and various skin paresthesias, as a result of delusional ideas.

Emotional Factors.—The question of the possible influence of psychic shock and emotions on the production of dermatoses is rather ignored by dermatologists. However, so reliable an observer as the late James Hyde[2] of Chicago stated his belief that psychic factors have a demonstrable effect on the color and nutrition of the skin, as well as on the production of exanthemata. He also called attention to the undeniable and hitherto unexplainable effect of maternal impressions on the skin of the fetus in the form of development of tumors and nevi. Pusey[3] also testifies to the possibility of emotional phenomena acting as etiological factors in skin diseases.

*Read before the Society of Neurologists and Alienists of Los Angeles, January 19, 1921.

With the recent advent of Freudian ideas, as it might be expected, clinical reports began to come in which incriminate sex repression, as a possible underlying factor in some dermatoses. Thus John Stokes[4] in 1918 reports a number of cases cleared up by psychoanalysis. Jelliffe and Evans[5] reported in 1915 a case of psoriasis, as a hysterical conversion mechanism. From a dermatologic point of view, however, the case is not convincing, as it has not been proven that psoriasis has been induced by psychic factors, neither that it has disappeared after the uncovering of the sex reflex.

The whole field of the direct causal relationship of psychic and emotional factors to skin lesions is as yet an unwritten chapter, still waiting for the initial research. So far as the indirect influence of psychic factors on skin diseases through the intermediate influence of the vegetative nervous system is concerned, it can be granted even now to a very large extent, on both clinical and theoretical grounds.

Neurogenic Factors Proper.—The source of the intimate connection between the nervous system and the skin is to be found in their embryologic relationship, as they both develop from the ectoderm. The localization of all the sensory nerve endings on the skin surface enhances still more this relationship. With the exception of the brain and the spinal cord, skin possesses, probably, the richest nerve supply of any organ in the body, both in the number of nerve fibers and in their variety. The involvement of the sensorimotor and the vegetative nervous system in skin diseases can be manifested in many ways, being either primary or secondary. The simplest and the most common form of involvement of the nervous system is to be found in chronic itching dermatoses, when through discomfort and loss of sleep the patient develops a neurotic condition or a fully marked neurasthenia. On the other hand, if an itchy dermatosis develops in an individual already neurotically tainted, this individual obviously is less capable to tolerate itching without scratching; this aggravates the local lesions and intensifies the itching still more, thus creating a vicious circle.

Nervous pruritus without any primary skin lesions is quite a common condition. It is the purest type of skin neurosis. There are several varieties of this nervous irritability of the skin. Winter and bath pruritus are some of the common types.

Reflex and Sympathetic Skin Symptoms.—There are several dermatologic phenomena which point unmistakably to the involvement of the nervous system, but which are not as yet satisfactorily explained. Such, for instance, is a spontaneous and sudden disappearance of benign growths, like warts, after they have persisted for many months. Also a spontaneous sympathetic disappearance of warts from one side of the body after warts of the other side have disappeared under exposures to the *x*-ray. The rapid extension of the inflamed area in dermatitis venenata way beyond the area exposed to vegetable or chemical irritants is also suggestive of the participation of the vasomotor nervous apparatus.

The radiation of itching and the projection of various skin paresthesias on the surface from the internal organs, such as the prostate gland in the male and the ovaries in the female, are examples of the true reflex neurodermatoses. However, in other cases reflex dermatoses must be taken in a broader sense. The reflex action must be extended also on the vasomotor and trophic nerves. The action is rather indirect and complex in nature. For instance, dentition eczemas in children cannot be explained by a direct reflex action. The sensory irritability radiating through the vasomotor nervous apparatus may induce a local hyperemia and may thus prepare a local circulatory predisposition for eczema. But the eczema itself should be attributed to the toxins arising from the digestive disturbances, induced by dentition, rather than to reflex action from the dentition itself.

Herpetic Group of Neurodermatoses.—The most striking illustration of skin lesions being produced as a direct result of the inflammation and degeneration of the nervous tissue is, unquestionably, *herpes zoster*. In the light of our present knowledge herpes zoster is merely a symptom pointing to the pathological changes of the respective posterior spinal root or ganglion. The nature of these changes, however, can be manifold. Streptococcal infection of the ganglion demonstrated by Rosenau represents only one type of herpes zoster.

Very similar to herpes zoster clinically stand various types of *herpes simplex*. With certain differences in localization and distribution, both conditions show a striking resemblance in the essential morphological features. The writer is inclined to side with Hartzell in the assumption that herpes simplex is merely an abortive and irregular form of herpes zoster.

Dermatitis herpetiformis morphologically stands very closely to the herpetic group. Its frequent development after a nervous shock and its association with emotional and mental strain strongly suggest a nervous etiology. The fact that the best therapeutic results are obtained from nervous and general tonics, such as arsenic, quinine, and strychnine, also points in this direction but whether the nervous system is involved directly or indirectly through some toxic influence is still a matter of conjecture.

Lichen Group of Neurodermatoses.—Among dermatoses of strongly presumptive nervous etiology must be mentioned *lichen planus*. Its frequent association with a state of nervous debility and exhaustion, as well, as its resolution and cure by rest and tonics, are facts strongly supporting this assumption. Here also can be properly mentioned *neurodermitis* of the French authors which by American and English writers is referred to the lichen group.

From the point of view of pathogenesis, neurodermatoses can be conveniently divided in the following groups:

1. *Functional neurodermatoses* in which skin lesions develop on the basis of general nervous irritability, exhaustion or toxaemia. Here belong nervous pruritus, lichen planus, dermatitis herpetiformis, and functional disturbances of the sweat and sebaceous glands. Until lately pemhygus used to be referred to this group, but recent research more and more suggests its infectious nature.

2. *Vasomotor neurodermatoses* represent a vast and clinically important group. Here belong erythromelalgia, angioneurotic edema due to the irritation of the vasodilators, and spastic anemic

forms, the extreme type of which is Raynaud's disease. It is of interest to note that the involvement of the vasomotor nervous apparatus in these cases may be merely secondary, as a result of focal or general infection and toxemia. In spastic angioneuroses, such as Raynaud's it is questionable, whether the arterial spasm is not secondary to the endarteritis obliterans associated with it.

3. *Trophoneurotic dermatoses.* Organic neurodermatoses or trophodermatoses are as yet very little understood. Our present knowledge is limited to the morphological characteristics of various clinical forms induced by trophoneurotic changes and the resulting degenerative phenomena. What nervous fibres, ganglia, or centres control the nutrition of the skin, is unknown. To the trophoneurotic dermatoses belong idiopathic skin atrophies, particularly those of the diffuse symmetrical progressive type, disturbances of pigmentation, both in the sense of superfluous deposit, and the loss of pigment, alopecia areata, indolent and perforating ulcers, scleroderma, etc.

Endocrinopathies. Closely identified with trophoneuroses are endocrinopathies. While endocrinous glands form a system of organs independent of the nervous system, yet their function is so closely interwoven with the vegetative nervous system and their secretory activity retroacts so strongly on the isceral nervous apparatus that the incorporation of endocrinopathies in the general pathology of the nervous system, as some of the modern neurologists do, seems to be fully justified.

The most important dermatologic syndromes due to the dysfunction of endocrinous glands are: myxedema due to hypothyroidism, the hyperthyroid skin syndrome observed in Graves' disease, bronze discoloration of Addison's disease due to the pathological changes in the adrenal glands, and the adiposogenital dystrophia due to the changes in the hypophysis. Besides these forms which are due solely to the dysfunction of endocrinous glands and are proven so conclusively, there is a number of dermatological conditions where the endocrinous dysfunction is only one of the symptoms and is coexistant with other pathogenetic factors; to such conditions belong: scleroderma, angioneurotic edema, pathological blushes and erythemata, vitiligo, etc. It must be kept in mind, though, that this division and strict separation of neurodermatoses into distinct groups—functional, vasomotor, trophic and endocrinopathic—cannot be maintained in all cases or even throughout the whole course of certain individual cases. All these branches and functional varieties of the vegetative nervous system may be involved by pathogenetic factors simultaneously, with one or another dominating in various cases, or in different stages of an individual case.

Clinical Significance of Neurodermatoses.—A fact of great clinical significance is that most neurodermatoses, particularly those of trophic, vasomotor, and endocrinopathic nature, are not independent clinical entities but rather symptoms or syndromes incidental to the complex picture of many organic neuroses. This fact largely explains why these dermatoses may have a manifold etiology and also why various organic neuroses may present quite a variety of skin manifestations.

For instance, scleroderma, as stated by Jelliffe,[6] may be observed in a number of neurological conditions, such as peripheral nerve palsies, spinal cord injuries, syringomyelia, poliomyelitis, and multiple sclerosis; it may be also of pluriglandular endocrinous origin and even psychogenic through the action of the thyroid.

Similarly Raynaud's syndrome may be traced to psychic factors (shock, hysteria, precocious dementia), to the cerebral and spinal lesions (hemorrhage, trauma, paresis, multiple sclerosis, tabes, syringomyelia, tumors). It may be also observed in peripheral neuritis, endocrinopathies, and arteriosclerosis.

On the other hand dermatological literature shows that organic neuroses may present a great variety of skin manifestations. Thus, according to Pusey, in locomotor ataxia may be observed erythemas, urticarias, herpes zoster, bullous eruptions, trophic ulcers, and gangrene; in spinal meningitis, erythematous, vesicular, and bullous rashes; in syringomyelia and lepra, anesthesia, trophic ulcers, pigmentations, erythemas, and urticarias; in peripheral neuritides herpes zoster, sensory disturbances of the skin, vasomotor and trophic disorders, atrophy and changes in the skin texture.

Conclusion.—On the bases of the observations above cited, nosologically, neurodermatoses should be accorded a position on the borderline between dermatology and neurology. The clinical recognition and morphological differentiation, as well as the local treatment, are within the specific field of dermatology. On the other hand the pathogenesis and systemic treatment fall within the sphere of neurology. Obviously, then, the clear and thorough understanding and the therapeutic control of neurodermatoses cannot be attained until a close cooperation and a joint study of the patient by neurologist and dermatologist will be a routine procedure in these cases.

In the present state of our knowledge neurodermatoses may not have a specific pathognomonic significance from the neurological point of view. They do, however, serve as a surface indication of functional or organic changes in the vegetative nervous system, and to this extent they can be of great service to the neurologist. This paper has for its purpose the emphasis of this very fact and is offered as a plea for a closer cooperation between neurologist and dermatologist in the joint study of this important group of dermatoses.

Rapidly Fatal Case of Epidemic Encephalitis.—Rabion reports a case of the hyperacute type in a man of seventy which terminated fatally in forty-eight hours. The subject was in apparently perfect health when stricken. Death naturally occurred in coma.—*Gazette des Hôpitaux.*

WHAT PRINCIPLE MUST GOVERN ESTIMATES OF VISUAL LOSS IN COMPENSATION CASES?

By WILLIAM MEHL, M.D.,
BUFFALO, N. Y.

In a former paper, published in THE MEDICAL RECORD of May 14, 1921, I discussed the question of what percentages of loss of use of an eye should be allowed for various degrees of impairment of vision, in Workmen's Compensation cases. My chief contention was that the figures of a Snellen test should be accepted for exactly what they are, the fraction merely being translated into the equivalent percentage of remaining vision, without attempting to minimize the loss by splitting vision into component parts. Simplicity, uniformity in the recording of results, and practical justice combined argue for the acceptance of visual acuity as vision in compensation matters.

There is urgent need of a fixed standard for determining degrees of depreciated eyesight. Solicitations by compensation boards and insurance carriers have caused individual oculists and ophthalmological societies to work out tables of various kinds. These tables, instead of solving the problem, rather have increased the existing confusion. The explanation for the great diversity of estimates, is that there is no agreement as to the point of view from which to attack the problem. And yet, the point of view is clearly indicated in the compensation laws of most, if not all, the States which have such laws. Believing this to be an important fact, possibly not generally known to medical practitioners, and persuaded that attention should be called to basic principles of estimating vision, within the limitations fixed by laws as they stand, I submit the present paper, in hope that the discussion may clear the way for a final solution.

My former paper has been criticised on the ground that I failed to take into account that the recorded fraction of visual acuity does not represent a corresponding fraction of loss of economic or industrial use of the eye. I am well aware of this. But I did not attempt to touch the question of economic or industrial loss at all and did not see any necessity for considering it, since practically all present State Compensation Laws disregard visual working efficiency altogether. Until this condition is changed, there would seem to be nothing gained by having oculists argue from a different point of view.

What is the Law?—Loss of use of eye is almost uniformly interpreted as loss of vision, and *vice versa*, by the compensation laws in the United States, and no account is taken of the vocational handicap sustained. The point may be argued, but there it is in the law, and those who rate eye impairments in compensation cases must be governed by the law as it stands.

The laws of Connecticut, Illinois, Indiana, Kentucky, Maine, Maryland, Massachusetts, Missouri, Ohio, Rhode Island, South Dakota, Texas, Washington, and West Virginia, and probably many other States, award compensation for "permanent loss" and "reduction of *sight*," "total or fractional part of *vision*," "irrecoverable loss of *sight*," "total and partial loss of *vision*."

In the New York law occurs the less explicit phrase "loss of use of eye." However, it is amply established that "loss of vision" is intended. I am informed that the Commission which administers the law has, from the very beginning of the operation of the law, made its awards for "loss of use of an eye" on the basis of visual acuity as revealed by Snellen tests. The Appellate Courts uniformly have sustained awards made on this basis, except that they compelled limitation to such loss of vision as remains after the highest tolerable correction by proper lenses. All this confirms the view I presented in my former paper.

Ohio has a provision which decrees that no compensation shall be allowed for "less than twenty-five per cent. loss of vision." It is obvious that 20/25ths of normal visual acuity is meant. Suppose the Milwaukee tables of 1919 were applied, then a person would get no compensation in Ohio, unless an accidental injury had reduced his visual acuity to at least 20/100ths of normal, which manifestly would be a gross injustice. I mention this merely in passing.

The assumption that physical impairment alone and not economic or occupational usefulness is intended, is confirmed by the schedules adopted in practically all the States which have enacted compensation laws. A watchmaker is paid compensation for exactly the same number of weeks as an unskilled laborer, when both have suffered an equal reduction of vision. A maker of fine tools is paid for no longer a period than a truck driver for the loss of an index finger. A man in a sedentary occupation gets as much for the loss of use of a leg as the man who has to climb telegraph posts or walk on elevated steel girders. The compensation is fixed for the limb and the organ which has been disabled permanently, regardless of the resulting occupational handicap or any other economic consideration.

My belief is that most of the legislatures in framing the laws assumed the practical impossibility of taking account of the thousand and one factors entering into the problem of fixing the reduction of earning power in individual cases, and decided to have compensation awarded on a basis of purely physical impairment alone.

We must remember that compensation is intrinsically an insurance proposition. The insurer must know beforehand what he will have to pay for a given injury, whether he is to meet losses of earning capacity or merely the physical impairment for which an arbitrarily fixed amount of compensation is allowed. The latter is the more easily determined of the two considerations. That makes it the more desirable from an insurance standpoint. In a case of visual impairment the findings of an ophthalmologist supply all that is required to settle the percentage of loss to be paid for.

It is exceedingly important that ophthalmologists should keep these things in mind. We are not experts on industrial questions, and therefore should not permit ourselves to substitute for purely scientific examination and report, opinions as to what we believe to be the proportionate impairment of *economic* visual efficiency.

Scientifically speaking, 20/40ths means 50 per cent. loss of visual acuity. As a matter of fact,

visual acuity is working vision. 20/40ths accordingly, represents loss of one-half the normal working vision of the eye. I feel that there cannot be too much insistence upon this point.

The latter statement has been called by one oculist "absolutely wrong and misleading," with the added comment that "were Snellen alive today he would be much chagrined at having his method so badly misconstrued." I cannot answer for what Snellen would say if he were alive today. What I do maintain is that if 20/20ths represents normal visual acuity or working vision, then 20/40ths is one-half of normal or fifty per cent. of normal, feeling reasonably sure that this is mathematically correct. I was not at all considering what constitutes blindness, in my former article, nor am I aware of any Snellen formula which represents blindness; therefore I cannot see why my statement should be criticised on the ground that 20/40ths is not the midway point between 20/20ths and blindness. All I contend is that 20/40ths means that normal visual acuity or working vision has been reduced exactly fifty per cent. by dropping from 20/20ths to 20/40ths.

As soon as a State legislature fixes *industrial* blindness at a given point, say 20/100ths or 20/200ths, and provides that all lesser impairments of sight shall be rated proportionately, we shall then have to assign to 20/40ths a different percentage. The State of New York last year amended the Compensation Law by fixing 20/100ths or "eighty per centum of the vision of the eye," as "the equivalent of the loss of the use of the eye." As no provision was added to govern awards below the "eighty per centum" mark, the Commission appears to have adhered to its former practice of merely translating the fractional figures of Snellen tests into the corresponding percentages, up to eighty per centum. There is, no doubt, ample justification for this. If, on the other hand, the Commission should take the initiative of grading partial reductions of vision in accordance with the percentage fixed as representing "the loss of the use of the eye," it would be equally right, and perhaps more consistently right, in adopting the following table of percentages:

	Loss		Loss
20/30ths =	12½ per cent	20/70ths =	62½ per cent
20/40ths =	25 per cent	20/80ths =	75 per cent
20/50ths =	37½ per cent	20/90ths =	87½ per cent
20/60ths =	50 per cent	20/100ths =	100 per cent

If another State should happen to have fixed upon 20/200ths as representing industrial blindness, and provided that lesser reductions of sight shall be graded accordingly, the percentages of loss would run like this:

20/30ths =	6¼ per cent	20/110ths =	56¼ per cent
20/40ths =	12½ per cent	20/120ths =	62½ per cent
20/50ths =	18¾ per cent	20/130ths =	68¾ per cent
20/60ths =	25 per cent	20/140ths =	75 per cent
20/70ths =	31¼ per cent	20/150ths =	81¼ per cent
20/80ths =	37½ per cent	20/160ths =	87½ per cent
20/90ths =	43¾ per cent	20/180ths =	93¾ per cent
20/100ths =	50 per cent	20/200ths =	100 per cent

In short, as soon as a point is arbitrarily fixed as representing industrial blindness, the percentages of loss of vision can easily be figured accordingly. This introduces, of course, an economic element which probably will be followed, in the course of time, by further modifications taking account of the comparative values of the loss of the first half of vision and that of the second half.

The wearing of correcting lenses constitutes a serious handicap for many workers, skilled and unskilled, in the open labor market. The upkeep of visual correction entails expense of considerable magnitude to laborers already set at a disadvantage by the wearing of glasses. Aside from all this, there is the undeniable fact that the 20/40ths eye has been deprived of most of its surplusage with which it was endowed by nature; and though this surplusage ordinarily may not be used, it was a possession of which the eye has been robbed.

To be sure, the loss of the first fifty per cent. of visual acuity is not as serious, economically speaking, as the loss of the second half. A homely example may illustrate the point. A man who is reduced from $5,000 to $2,500 a year, has lost actually one-half of his income, and no amount of camouflage can change the fact. Nevertheless the practical effect of the loss of the first $2,500 is not as serious as the loss of the second $2,500 would be. Every smallest loss *below* the 50 per cent. line will of necessity increase the hardship of his situation, until the man becomes altogether dependent upon others for aid. And yet, the loss of a surplusage in dollars and cents is not to be compared with the loss of the surplusage of vision. A man may save up money for times of reduction of income. The eye cannot bank its surplusage; when this is gone, the remaining vision is all it has to carry it through the future.

By way of parenthesis, and as a matter of practical experience, I should advise that no final award be made in cases of partial loss of vision, particularly not when the impairment is due to scarring of the cornea, before the expiration of twelve months from the day of accident.

The proposition that 20/40ths means loss of 50 per cent. of normal visual acuity, or working vision, was accepted universally as final until insurance carriers had to pay for percentages of such reduction, by the operation of compensation laws, when efforts naturally began to be made to minimize the percentages of partial impairments of sight, by urging the suggestion that visual acuity is only one factor of vision.

Component Parts of Vision Per Se.—Of course, visual acuity is not all there is of vision. Peripheral vision is a most important factor. So is binocular vision. We might go on and add color perception, which is common to both central and peripheral vision, and it is, therefore, a separable factor. Moreover, color perception undoubtedly is a necessary qualification for many occupations. However, there is no need of dividing vision into theoretically separable component parts.

Color perception is given no consideration even in the tables which purport to make allowance for every kind of vision. Binocular vision is eliminated by law in the State of New York in that its impairment is made equivalent to the loss of an eye. That leaves peripheral vision. It may well be argued that credit should be given for this in the rating of eye impairments. Theoretically the proposition is correct. Practically it does not work. All of us know this. The time required for examination is a serious item. Furthermore, an accurate estimate of the percentage of existing peripheral vision, in a given case, is almost impossible. No two oculists

would ever agree in their ratings, and compensation boards would lose confidence in our findings generally.

Visual acuity is the practical working vision. It is the vision most frequently destroyed or reduced by industrial accidents. Traumatic impairments of peripheral vision by itself are so rare that it would seem unjust to reduce the allowance for the ordinary eye injuries by suggesting that only one kind of sight has been affected. When there is an extremely rare case of destroyed peripheral vision, then is the time to take up this matter for special consideration.

The compensation for eye injuries is small at best, perhaps because payment on the basis of visual acuity was assumed. If a different basis is to be put in operation, we shall no doubt hear that the number of weeks for which compensation is payable must be increased to provide for more adequate pay.

For all these reasons I adhere to the proposition that vision should be interpreted as working vision, which is visual acuity, estimated after correction by lenses. In other words, the highest degree of visual acuity obtained, with correction by lenses which the eye will tolerate, as expressed in the Snellen figures, should determine the percentage of vision remaining. If a different interpretation is to be substituted, the legislature will have to make the first move and establish a new principle of insurance for eye injuries.

Economic Factors.—The principle of *economic* loss may, in the course of time, find universal approval and acceptance in compensation legislation in the United States, but it has not done so to an appreciable extent thus far. Until this is done, compensation will continue to be made for the nature of the injury by itself and loss tables based on assumed impairment of partial use will be disregarded. The awards must accord with the law or they will fail to pass the test of review by courts of appeal.

In several European countries the economic factor is, and has long been, the supreme and deciding consideration. There the injured are paid for losses of earning capacity sustained in the pursuit of their particular trades as long as they live. A representative of the trade to which the injured person belongs sits in an advisory capacity, with the government officer, who makes the award, to determine the decrease of occupational efficiency. Aside from the frank acknowledgment of class distinction among the workers, there is back of the proposition a system of state monopoly of compensation insurance. The latter fact furnishes one reason why the principle of economic loss is not likely to make rapid headway in the United States. Keeping a case of permanent impairment of every kind open during the life time of the afflicted must in the end lead to exclusive state insurance, as private companies would not be able to carry the many large reserves required to cover such cases. And as regards classification of workmen by trades and occupations, we shall meet with equally strenuous objection springing from the experience that, with us, men turn frequently from one line of work to another; even those who have learned a trade do not always stick to it. All of which makes it difficult to persuade a legislature to depart from the present simple plan of making purely physical loss determine for how long a period the injured shall receive compensation.

The only State I know of where the reduction of earning power must be considered when awards are made in permanent partial disability cases is California. The provision in question reads as follows: "In determining the percentages of permanent disability, account shall be taken of the nature of the physical injury or disfigurement, the occupation of the injured employee, and his age at the time of such injury, consideration being given to the diminished ability of such injured employee to compete in an open labor market."

In the principal Canadian Provinces, the European principle of payment of compensation for permanent partial disabilities, "during the life time of the employee," obtains to some extent. For example, Section 38 of the law of Ontario reads:

"(1) Where permanent partial disability results from the injury the compensation shall be a weekly payment of 55 per cent. of the difference between the average weekly earnings of the workman before the accident and the average amount which he is earning or is able to earn in some suitable employment or business after the accident, and the compensation shall be payable during the life time of the workman.

"(2) Where the impairment of the earning capacity of the workman does not exceed 10 per cent. of his earning capacity instead of such weekly payment the board shall, unless in the opinion of the board it would not be to the advantage of the workman to do so, direct that such lump sum as may be deemed to be the equivalent of it shall be paid to the workman.

"(3) Where deemed just the impairment of earning capacity may be estimated from the nature of the injury, having always in view the workman's fitness to continue the employment in which he was injured or to adapt himself to some other suitable occupation."

In British Columbia, the law is practically the same.

In Ontario and British Columbia the Province has its own Accident Fund and excludes private insurance of compensation.

In Quebec the employee is entitled "in case of permanent and partial incapacity, to a rent equal to half the sum by which his wages have been reduced in consequence of the accident." The total amount may be commuted to a lump sum of not more than $2,500. The latter clause was found desirable no doubt because in this Province private insurance is permitted, but every company must deposit with the Government of Canada or the Province of Quebec "an amount deemed sufficient to insure the performance of its obligations."

A Middle Course.—As suggested before, I doubt whether the economic principle will win its way to anything like universal acceptance in the United States. But there is a middle way, and it may be worth while to consider it: Instead of taking account only of the physical depreciation, or making the actual economic loss sustained, in each particular case, the determining principle, the legislature might be persuaded to fix for every fraction

of vision, as established by Snellen tests, a percentage of loss assumed to represent the impairment of the general economic usefulness of an eye, and this percentage to apply in all cases, regardless of the particular occupation of the injured individual, as is now being done in cases of amputation or ankylosis of fingers, arms, legs, etc. We should then be able to agree that, while 20/40ths means 50 per cent. loss of visual acuity, it does not mean that the injured eye has lost one-half of its general *industrial efficiency*.

The simplest plan would seem to be, as I have suggested before, that the legislature should fix the point, or percentage, of visual acuity which is to be considered the equivalent of industrial blindness (as has been done by the State of New York, for example), and then require the minor losses to be graded accordingly. The two tables of percentages included in this article indicate what I wish to convey.

Committees of employees, employers, oculists and insurance carriers should have their say in the matter. The legislative committee charged with the working out of the proposed revision of the law would then be in position to enact fixed standards of visual efficiency, which though in a measure arbitrary, would represent what is deemed a just interpretation of the Snellen figures, when applied to industrial loss.

I repeat, for I consider the point most important, the change from the present basis of insurance to one wholly different in principle demands serious consideration. The logic of economic interpretation leads of necessity to keeping cases of permanent partial impairment of vision open during the life time of the injured employee; correcting glasses must be supplied whenever needed, there must be periodical reexamination of the eye, etc. The suggestion is also implied that nothing short of exclusive state insurance can meet the situation ultimately if the economic loss principle is to be applied with all its logical consequences.

The middle way I have suggested may not work such far-reaching changes but the germ of the principle is there, and history shows that a principle is bound to affect more or less the whole structure in the course of time.

Summing Up Conclusions.—Where the law provides that compensation shall be awarded for a partial reduction of vision, examination by Snellen tests will establish what fraction or percentage of vision is lost. While these tests are confined to visual acuity, they are for all practical purposes the only reliable means for fixing loss of vision in general, as I tried to prove in my former paper on the valuation of visual impairments. Tables fixing what amount of peripheral vision shall be assumed to exist when a certain fractional loss of visual acuity has been established, are arbitrary and unscientific.

Loss of binocular vision is legally considered, in the State of New York at least, as equivalent to the loss of use of one eye. So this factor cannot be brought in to minimize the sustained impairment.

If instead of the principle of insurance of physical impairment *per se* there is to be substituted the principle of economic loss, then the legislature will have to make the first move and determine a new governing basis for compensation awards. The logic of industrial, occupational, vocational or by whatever other adjective the loss may be characterized, when the economic factor becomes the basic consideration, must of necessity lead to ultimate state monopoly of compensation insurance. These are matters which are of no direct concern to oculists as such and may well be left to be settled by experts in other departments of work.

I have indicated a middle way which may bridge over the transition from compensation for the purely physical impairment of sight to compensation for the actual loss of earnings caused by a traumatic reduction of vision in each individual case. The middle course would take account of the loss of useful vision in a very general way by fixing the point of industrial blindness and requiring lesser impairments of sight to be rated by appropriate percentages. This course, too, must first have the sanction of legislative enactment before compensation boards can permit themselves to be governed by it.

417 Franklin Street.

OCCUPATIONAL THERAPY IN MENTAL HOSPITALS.

AN ADMINISTRATOR'S VIEWPOINT.

By J. ALLEN JACKSON, M.D.,

DANVILLE, PA.

SUPERINTENDENT OF THE STATE HOSPITAL.

Revivals in the commercial, scientific and medical worlds are not uncommon and from decade to decade there is a revival in medicine of old ideas, old signs, and old forms of treatment. Many of these revivals are timely, and especially so is the revived interest in employment as offered in the treatment of diseases.

Employment has been practised in medicine, especially in mental medicine, since the early days of asylum treatment. Certain features, however, have been added which have given it a decided field of usefulness and the agency is now referred to in a general way as occupational therapy. Occupational therapy therefore may be defined as any form of occupation so directed as to meet certain definite therapeutic indications; the term occupational relating to a state of being busy.

Although the majority of mental hospitals in the United States are employing some form of occupational therapy (that is interpreting occupational therapy, as any "busy state" which benefits the patient's mental condition), the grade and form of therapy used range from ward cleaning to skill in arts and crafts, with a total percentage of patients employed showing a wide range of latitude.

It is difficult at the present time to determine whether a hospital is making every use of occupational therapy owing to the lack of general standardization. Provision for an occupational teacher on the pay roll gives no index to the amount of this form of therapy used. Neither does the lack of one imply any great significance, as many of the mental hospital nurses are well versed in certain forms of occupational therapy, and work is being carried on with a fair degree of efficiency. To draw conclusions, therefore, one must make an

analysis of the form of therapy used and its application.

The administrator, therefore, should establish a definite standard as a guide to carry on the work. A great step in this direction would be to determine first what should be included under the head of occupational therapy; what are to be the subheadings, if necessary. It would seem that all the patients formerly grouped under the heading of employment, diversion, recreation, and exercise, plus those who are enjoying that form of therapy known as invalid occupation, would be grouped under the general heading of Occupational Therapy, and further subheadings used if necessary such as those just enumerated.

Indication for Occupational Therapy.—No one thinks of the successful application of occupational therapy to every patient in the mental hospital. A definite number of dements, unclean and untidy cases in a hospital, will always prevent such an accomplishment. Upon the other hand, an assistant physician has not done his duty by his patient until he has tried on the individual cases some form of occupational therapy before passing them on to the hopeless group.

From the executive standpoint several grades of patients present themselves and each requires a special therapy. Briefly stated, these are as follows: (1) Acute cases; (2) infirm bed cases; (3) refractory and untidy cases; (4) convalescent cases; (5) mildly chronic cases (workers). Occupational therapy should be available for each group.

Personnel Required.—To obtain the best results from this agency we have available physicians, artisans of trades, nurses, and those persons specially trained in occupational therapy. In building up the personnel of a hospital, however, definite questions come up: (1) What is the duty of the specially trained occupational teacher in a mental hospital; (2) are we making the best use of occupational teachers? (3) is occupational therapy so intricate that pupil nurses cannot grasp it or is the subject of such a special nature that it requires training in special schools?

In answering the above questions seriatim I should say (1) instructors and demonstrators of occupational therapy to the student body; (2) no, as we make very little provision for teaching occupational therapy in our training school for nurses; (3) no.

Before planning for such an organization one realizes the large scope of the work. The close relation of such work to the duties of the ward nurse and her assistant; the conflict of authority of therapist and nurse if we organize efficiently such a service independently of the nursing service. It may be granted that in the arts and crafts room and the industrial buildings, the specialist may find a useful field, but here they may be replaced by artisans of definite trades, as cabinet makers, shoemakers, tinsmiths, seamstresses, etc. The logical personnel therefore seems to be the physicians, trained nurses, occupational instructors, and artisans of well established trades, each being assigned to specific duties.

Place of Application.—The acute cases may be provided with occupation at the bedside, singly or in groups or in a special room of the acute section. When an acute case goes to the arts and crafts room or industrial building, he or she, would seemingly no longer be classified as an acute treatment case, but an acute convalescent case. The work should be light, diverting, and not too tiresome.

For the infirm bed cases, who partially recline during the day, and the wheel chair cases there should be a special form of therapy applied, something light, pleasant and diverting.

The convalescent groups could best adapt themselves in the arts and crafts room or in the industrial buildings.

Our refractory and unclean group requires a special room on the ward.

The mildly chronic are best engaged in utility work, outdoor work, manufacturing, agriculture, truck farming, etc.

Organization of the Work.—From the foregoing statements the reader has already formed an idea as to the scheme of organization the writer is to suggest. Primarily occupational therapy, as all other therapy, is within the province of the physician and he should decide as to indications and contraindications of occupational therapy and the forms best adapted for the individual patients. The question, therefore, resolves itself into mapping out a definite system which will mould in the medical service. The scheme should include a supervising physician, assistant physician, charge and pupil nurses and an instructor and demonstrator of occupational therapy with properly manned arts and crafts rooms, industrial rooms, agricultural units, etc. The scheme should make available forms of occupational therapy for the acute cases, infirm cases, refractory cases, convalescent cases, and the mildly chronic cases.

The supervision of the entire administration should be under the direction of a trained psychiatrist, preferably the assistant medical superintendent. He should be familiar with the ward assignments, the class of patients treated therein, and the forms of occupational therapy provided by the hospital. In a general way he should check the assistant physician's activities in this phase of the work.

Role of Assistant Physician, Nurses and Instructors.—To the assistant physician we look for the most fruitful rewards. On him and the charge nurse rests the greater part of the responsibility of success or failure of occupational therapy. He should know the patients and the form of work which would best meet the needs of the patient's physical and mental condition. He should bear in mind the possibility of recovery of the patient as well as the possible chronic nature of the disease; training his patient so that he will be fitted ultimately to render some economic service to the hospital.

The stepping stones should be from bedside to convalescent, to arts and crafts, to industrial buildings, to service departments, and to agricultural departments. Each service, therefore, would be a developmental department, as it were, training the patient to attain a more useful type of employment. The type of patient and his former occupation may preclude the necessity of such a course of procedure and the patients may be assigned directly to any of the services. The charge nurse should see that the

work is carried on, and her work in turn should be checked by the superintendent of nurses.

The arts and crafts room should be supervised by a nurse who is well trained in the arts of occupational therapy. The industrial building should be manned with the highest type of men, who are artisans of their trades, one of whom shall be the chief of the department and held responsible to the administrative head of the hospital for the efficient and economic administration of the same.

Records.—Individual card records should be kept of the patient's work, the hours employed, the progress of the patient's mental and physical condition. The cost records seem unnecessary in those groups confined strictly to ward service, for it is a part of the medical service, and the charge of the organization should be borne by the medical service, as are drugs, bandages, etc. In the industrial buildings, however, and in the arts and crafts rooms, a definite record should be kept of the stock on hand, materials received, articles made, and disposal of the same. The work of the industrial departments usually consists of making articles required by the hospital. In the arts and crafts room the materials are usually made for sale, the proceeds of which revert to the patients' general entertainment fund and the purchase of new supplies, as materials used here should not be charged to maintenance.

At the State Hospital for Insane, at Danville, we find the application of occupational therapy more thoroughly checked by grouping all activities of patients under one general heading of occupational therapy and permit three principal subheadings such as occupied usefully, otherwise occupied, and unoccupied. The first heading is well understood. The second heading includes all patients who exercise, read, write, attend chapel, etc. The third designates the hopeless cases and those too acutely ill to appreciate occupational therapy.

Calculations are easily based on such data. For example, in the female department, with a population of 789 patients, 611 (77 per cent.) are enjoying some form of occupational therapy. Of these 421 (53 per cent. total population) are usefully occupied, while 190 are otherwise occupied and 178 are hopeless cases. In the male department we have 850 patients, 684 (80 per cent. of the total) of whom are enjoying occupational therapy. Of these 468 (55 per cent. of the total) are usefully employed, 216 otherwise occupied, while the remaining 176 are hopeless cases.

The foundation of such a system was laid at the Danville Hospital at an early era of the hospital by Dr. S. S. Schultz and added to by his successor, Dr. H. B. Meredith. The present administrator hopes to add one more stone in the building of the work by placing the administration under the general supervision of the assistant medical superintendent, the employment of an instructor and demonstrator of occupational therapy, the teaching of occupational therapy in the training school, instituting patients employment cards and carrying more of the work to the bedside of the acute and infirm cases.

Summary.—1. There is a need of a definite standardization of occupational therapy.

2. Occupational therapy should be provided for all types of cases.

3. Trained physicians, nurses, and skilled artisans of trades are required for the personnel.

4. Occupational therapy should be included in the curriculum of our training schools for nurses.

5. Occupational teachers should be employed for the purpose of teaching and demonstrating occupational therapy to the student body.

6. Suitable physical conveniences must be provided to carry on the work.

7. A definite organization is required to obtain the best results.

8. A definite amount of record keeping is required.

PROCTITIS AND SIGMOIDITIS.

By CHARLES J. DRUECK, M.D.,
CHICAGO, ILL.
PROFESSOR OF RECTAL DISEASES, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

PROCTITIS, or inflammation of the rectal mucosa, is of much more common occurrence than is generally supposed. The anatomy and physiology of the rectum and sigmoid renders these organs very susceptible to catarrhal changes. The crypts in the mucous membrane are potential pockets for the lodgment of infectious material. The venous circulation, being in the opposite direction to the fecal current, always is sluggish. In the colon the fluids are absorbed from the food débris. Here, toxins pass into the lymphatics and enter the circulation. As the fecal mass hardens, it excoriates and sometimes actually tears the mucous membrane as it is being expelled. These chemical and mechanical irritations frequently repeated result in catarrhal proctitis. As the rectum, sigmoid, and colon have the same structure and function, the same catarrhal disturbances affect all parts. However, it often is hard to explain just why the disease is so localized in a given case. So-called catarrhal inflammation of the intestinal mucous membranes (an inflammation that cannot be accounted for by the presence of any of the now known bacteria) is very common, especially in the cities, where modern methods of living subject persons to over-indulgence in highly seasoned and stimulating foods and the maintenance of high nervous tension, together with lack of outdoor exercise. Our individual powers of resistance vary so much that some seem to maintain good health in spite of these adverse conditions, while others become indisposed on the slightest exposure or indiscretion; even a change of drinking water will in certain individuals cause a constipation of the colon or rectum. The onset of these catarrhal changes sometimes is insidious, and it may be impossible to define accurately the beginning pathological changes, because of the difference of temperament and habits in individuals. The prominent symptoms of inflammation in any part of the colon are referred reflexly to the rectum, and it may be added that the inflammation is seldom confined to any locality; it may begin either in the cecum or the rectum and spread the whole length of the colon.

There are many other inflammatory invasions of the rectal mucosa due to gonorrhea, syphilis,

dysentery, or diphtheria, but, excepting dysentery, these specific forms of infection are secondary to similar infections elsewhere.

Acute Proctitis.—Acute catarrh of the rectum, like that involving any other mucous membrane, comes on suddenly, and it may usually be traced to a definite cause. The onset is characterized by a chill and an elevation of temperature. There is a sensation of fulness, weight, heat, and burning in the rectum, or in severe cases actual pain, which radiates to the sacrum, the other pelvic organs, or down the thighs. Irritation of the trigonum vesicæ causes frequent micturition, tenesmus, and sometimes retention of urine. The rectum feels full, the anal sphincters are contracted, and there is a constant and ineffectual desire to empty the bowels. The feces, usually liquid, are forcibly ejected through the small orifice. This constant straining produces prolapse of the mucous membrane, especially in children. The patient always is more comfortable lying down than when up and about. During the first twenty-four hours the discharge from the rectum is liquid fecal matter; later, the engorged mucous membrane bleeds and the discharges are tinged with blood and contain mucus. In very severe cases, the mucous membrane will ulcerate and pieces slough off, accompanied with considerable discharge of clear blood. From this time the discharges contain mucus and blood mixed with feces.

An early and persistent symptom is the constant rectal tenesmus. The patient has a frequent and urgent desire to go to stool, but each time voids only a few ounces of liquid material accompanied with much straining and pain. The anus is red and painful, the sphincter irritable and spastic, and the introduction of the examining finger or the speculum is so painful as to necessitate an anesthetic. In the early stages the parts feel dry, feverish, and swollen to the touch; later, after secretion has started, the surface is moist and slimy, but the walls are so swollen as to seem closely approximated. Specular examination at this stage reveals a bright red, dry, and edematous mucous membrane, but later we find ulcerations. These ulcerations may be limited to one or two small points or there may be many foci, some of which may be quite deep and involve the whole thickness of the mucous membrane, even perforating the gut. When ulceration occurs above the peritoneal fold, it may cause peritonitis; when below that line, an abscess may result. Chronic or recurring proctitis in this way may cause a stricture.

Etiology of Acute Proctitis.—Among the causes of proctitis the following may be mentioned: Irritants directly attacking the mucous membrane, such as worms, highly seasoned foods or hard substances in the fecal mass, for instance, fish bones and hulls of cereals. Fecal irritants are common causes both of the acute and the chronic type. Constipation and fecal impaction of the rectal pouch alternating with periods of liquid feces often induce a sudden inflammation of the sigmoid flexure and rectum, or the rectal disturbance may be an extension of colitis resulting from the passage of the irritating discharges from above. Seasonal changes of food or water, particularly during the summer, or sitting on a cold, wet seat often are exciting causes. In all of these conditions, sudden and violent changes are important factors. Proctitis may result also from the use of strong purgatives, irritating suppositories, or as an extension of inflammation from hemorrhoids, prolapse of or eczema about the anus, or from disease of the neighboring organs, such as the bladder, prostate gland, vagina, or uterus. In a few instances, new growths within the rectum, such as polypi, adenoma, villous growths, and papilloma, also intussusception, occasion periodic exacerbations or protract the chronic proctitis.

Treatment of Acute Proctitis.—The treatment of acute proctitis varies considerably with the exciting cause, and therefore a thorough examination must be made before instituting any treatment. The parts being irritated and inflamed, the examination is very painful, unless an anesthetic, general or local, is administered. In many instances where for various reasons chloroform should not be given at the time of the examination, the patient may be relieved of most, if not all, of the pain by the application of a 2 per cent. solution of novocaine. A general anesthetic has much in its favor, because, while the patient is thus asleep, the sphincter may be thoroughly dilated, in that way relieving the tenesmus and greatly facilitating subsequent examination or treatment; at the same time, any local trouble or cause of the proctitis may be removed, thereby accomplishing two things at one sitting.

The first indication for treatment naturally is to remove the cause. Impacted feces or foreign bodies must be removed carefully so as not to injure the mucous membrane. The anal sphincters should be dilated, to permit easy and free emptying of the rectum. Decomposed, irritating, infectious intestinal contents should be removed by means of a saline cathartic, which should be taken in sufficient doses to produce a watery stool and a free flushing. After the bowel has been thoroughly emptied, it should be irrigated two or three times during the day with physiologic salt solution at 110 degrees.

For this irrigation the patient should be placed in the lateral prone position, with the hips elevated; the irrigator-reservoir being held one and one-half or two feet above the body. The irrigator tip should have a large return flow to allow free exit of débris. The solution is allowed to run into the bowel at a slow rate. Douching in this manner washes out a large amount of infectious material, such as secretions, fecal accumulations, and multitudes of microorganisms; it dissolves mucus and pus, flushing them out as shreds; also it contracts the vascular structure, thereby stimulating circulation, relieving the local congestion, and depleting the tissues.

Following the douche, about 2 drams of astringent antiseptics or other medicinal mixture is injected and the patient is instructed to retain it; at 1:5000 silver-nitrate solution being the most reliable. If the pain and tenesmus are not relieved, a 1-2-grain opium suppository may be inserted. These flushings are to be continued as long as there is any discharge of mucus or pus.

Enemas cannot be substituted for the irrigation, as they increase the tenesmus.

If the symptoms continue after the third day under this treatment, it will be found there are ulcers on the rectal wall, and these must then be treated locally. The patient is placed in the knee-chest position (which secures atmospheric dilatation), then a speculum is introduced and the entire rectum is inspected. Any ulcer present is wiped free of mucus or débris and painted with pure ichthyol or a 5 per cent. silver-nitrate solution.

The Diet in Acute Proctitis.—The diet should be carefully arranged so as to be absorbable and non-irritating and of such a quality as will insure soft or semisolid evacuations. A largely absorbable dietary is advisable also, in order that the bowels may move less frequently, thus diminishing the deleterious peristaltic movements. Milk should be excluded because it gives rise to hard, irritating curds in the feces. Fibrous vegetables, such as cabbage, kraut, celery, and green corn, are also forbidden, for they irritate the bowel. In their stead gruels of oatmeal, rice, and barley, egg albumen, gelatin, meat broths, and the proprietary prepared foods and peptones should be ordered. Water should be drunk freely and a full glass of flaxseed tea at night. This latter acts as a mild laxative, while also soothing the intestine.

Flaxseed Tea Recipe.—Take five tablespoonfuls of whole, unbruised flaxseed, pour over it a quart of boiling water and boil for ten minutes, strain through muslin while hot, flavor to suit by adding, before cooking, one teaspoonful of pulverized licorice, or one lemon, or ten drops of oil of peppermint or wintergreen, and two tablespoonfuls of sugar, or after cooling add a wine glass of wine. Make the tea fresh each day.

The patient should be kept in bed until all pus and blood have disappeared from the stools, because, when he is up and about the pendent position of the blood vessels, together with the thinness of their walls, and the associated congestion and inflammation, give rise to venous stasis, which seriously impedes or even prevents regenerative changes.

30 North Michigan Avenue.

Medicolegal Notes.

Physician's Immunity Under Harrison Act Limited to Appropriate Bounds of Professional Practice.—In a prosecution for violation of section 2 of the Harrison Anti-Narcotic Act the evidence showed that "the defendant was a practising physician in Pittsburgh, registered under the act so as to be allowed to dispense or distribute opium and its derivatives without a written order in official form 'in the course of his professional practice only'; that he was in the habit of issuing prescriptions for morphine sulphate without such written order and not in the ordinary course of professional practice; that he issued them to persons not his patients and not previously known to him, professed morphine users, for the mere purpose, as the jury might find, of enabling such persons to continue the use of the drug, or to sell it to others; in some cases he made a superficial physical examination, in others none at all; his prescriptions called for large quantities of morphine—8 to 16 drams at a time—to be used 'as directed,' while the directions left the recipient free to use the drug virtually as he pleased. His charges were not according to the usual practice of medical men, but according to the amount of the drug prescribed, being invariably one dollar per dram. All the prescriptions were filled at a single drug store in Pittsburgh, the recipients being sent there by defendant for that purpose; and persons inquiring at that drug store for morphine were sent to defendant for a prescription. The circumstances strongly tended to show cooperation between defendant and the proprietors of the drug store. At and about the dates specified in the indictment—the spring of the year 1917—and for more than two years before, the number of prescriptions issued by defendant and filled at this drug store ran into the hundreds each month, all calling for morphine sulphate or morphine tablets in large quantities." Affirming a judgment of the Federal district court for the Western District of Pennsylvania, overruling a motion in arrest of judgment of conviction, the Supreme Court of the United States says, in part, by Mr. Justice Pitney: "In each case where defendant was found guilty the evidence fully warranted the jury in finding that he aided, abetted, and procured a sale of morphine sulphate without written orders upon a blank form issued by the Commissioner of Inland Revenue, and that he did this by means of a prescription issued not to a patient and not in the course of his professional practice, contrary to the prohibition of section 2 of the act. Manifestly the phrases 'to a patient' and 'in the course of his professional practice only' are intended to confine the immunity of a registered physician, in dispensing the narcotic drugs mentioned in the act, strictly within the appropriate bounds of a physician's professional practice, and not to extend it to include a sale to a dealer or a distribution intended to cater to the appetite or satisfy the craving of one addicted to the use of the drug. A 'prescription' issued for either of the latter purposes protects neither the physician who issues it nor the dealer who knowingly accepts and fills it. Webb v. United States, 249 U. S. 96, 39 Sup. Ct. 217, 63 L. Ed. 497."—Jin Fuey Moy, 41 Sup. Ct. 98.

Regulation Requiring Monthly Morbidity Report Not Unreasonable, but Knowledge of It Not Presumed.—The Mississippi Supreme Court holds that under the Code of 1906, § 2489 (Hemingway's Code § 4838), empowering the State Board of Health to make and publish all reasonable rules and regulations necessary to enable it to discharge its duties and powers and to carry out the purposes and objects of its creation, a regulation requiring every licensed physician practising in the State to file a morbidity report on the first day of each month is not unreasonable. But, in the prosecution of a physician for knowingly violating such regulation, where the evidence wholly failed to show that the defendant had any knowledge of its existence, or that there had ever been any such publication of the regulation as to charge the defendant with knowledge of it, a peremptory instruction requested by the defendant should have been granted. There was no presumption that the defendant had knowledge of a rule or regulation of the State Board of Health. Conviction of violation of the regulation was reversed and defendant discharged.—Smythe v. State (Miss.), 86 So. 870.

Physician's Evidence as to Condition of Wound Three Months After Injury Competent.—In an action for personal injuries, the testimony of a physician who had not examined the plaintiff until about three months after the occurrence as to finding the wound discharging serum and pus, and that upon probing the sinus he had discovered a spicule of dead bone there, and his further testimony that such a condition might result although the treatment was skilful and proper, was held competent. Whether or not this condition was one of the natural consequences of the accident was a question for the jury.—Schuh v. Oil Well Supply Co. (Cal.), 195 Pac. 703.

Statute as to Advertising Held Constitutional.—The California District Court of Appeals, Second District, holds that Cal. St. 1917, p. 111, § 14, subd. 3, providing that the board of medical examiners may revoke the license of a physician or surgeon advertising so as "to deceive the public or impose upon credulous or ignorant persons, and so be harmful or injurious to public morals or safety" is not unconstitutional as denying to citizens the equal protection of the law or as being class legislation; and is not void for uncertainty or indefiniteness. —Glass v. Board of Medical Examiners of California (Cal.), 195 Pac. 73.

ACHONDROPLASIA.

ACHONDROPLASIA presents a quite different aspect in the fetus from that in adults. In the fetus the hereditary antecedents are varied; achrondroplasia may be noted in one of the ascendants, but there is no rule in this respect. The same applies to syphilis, at birth the achondroplasic infant offers a very marked disproportion between the head and limbs, while the trunk is normal in size. The skin is often thick, forming numerous folds, and appears to be too abundant for the body it contains. The macrocephaly mentioned by some observers is usually only apparent, but forms a striking contrast with the micromelia which generally involves the four limbs, their segments being short and thick. The muscles are well developed, while the bones are short and thick with very large epiphyses. They are sharply curved, thus distinguishing them from the bones of rickets, the apex of the bend being at the union of the epiphysis with the diaphysis.

Achondroplastic infants offer nothing in particular as far as their growth is concerned. They walk at the usual time, the intelligence is an average one, and the development of the genital organs is normal. The peculiar dwarfish state is what strikes the observer as they have the appearance of small athletes, because the muscular system is well developed. The achondroplasic adult presents, besides the above mentioned characters, a very marked brachiocephalic head, and a rhizomelic micromelia as Péloquin showed long since; the arm is shorter than the forearm; the thigh than the leg, although the hands and feet are short and thick in all their parts, the shortening of these terminal segments is not proportional to that of the intermediary segments. The skeleton of adult achondroplasics presents less considerable deformities than that of the fetus; the bends in the bones are less sharp and are not constant. Radiography shows that consolidation of the epiphyses is considerably delayed while the pelvis is narrowed in all its diameters from arrested development of the iliac bones.

The histological structure of the achondroplastic osseous system is not as yet perfectly clear and quite contrary opinions exist. The term chondrodystrophia fœtalis has been given by Kaufmann to this process and he divides the affection into three principal varieties. (*a*) Chondrodrystrophia malacica, met with only in the fetus, characterized by shortening and softening of the bones of the entire skeleton; (*b*) hypoplastica, or normal type, and (*c*) hyperplastica, characterized by an exuberant disordinated ossification. Some observers regard these three forms as three different phases of the same process, and in point of fact they have not been differentiated histologically.

From an essentially clinical viewpoint, the process may be divided into a partial type, an atypical type, and a complex type. In the generalized type the lesions involve the ribs, clavicle, and vertebræ. In the partial type—which for some is of great importance—the lesions are localized in one or several limbs. Beside the atypical types, which are of clinical interest only, are to be placed the complex types—an achondroplasic subject may become syphilitic or rachitic, so that the differential diagnosis becomes difficult in absence of a histological examination, and these complicated cases are not very uncommon.

The pathogenesis of achondroplasia is still most uncertain but first of all this process must be distinctly separated from rickets. Independently of their differential characters these two affections present a distinct difference in their respective evolutions. Achondroplasia is a congenital affection undergoing its evolution during intrauterine life and has become cured at the time of birth. Achondroplasia may assume the appearance of rickets, but in one case it has been shown that the process was essentially a sclerosis of the cartilages of conjunction undergoing multiplication. The theory most generally accepted for explaining the origin of achondroplasia is based upon intrauterine autoinfection or intoxication which acts either directly on the cartilage or on ossification, or indirectly by the intermediary of certain glands—thyroid—or by the nervous system—trophic disturbances. The old opinion of Perrot, that achondroplasia is a dystrophy of primordial cartilage resulting from an hereditary primary change in the germ of the cartilage has now some partisans, but the pathogenesis is not altogether clear and the affection may, without doubt, be divided into a certain number of forms having different origins.

PURULENT METASTATIC PANOPHTHALMIA.

DURING infectious diseases—suppurating phlebitis, purulent otitis, puerperal infection, chronic bronchitis with bronchial dilatation, etc.—a patient may notice that his sight is becoming impaired. In a very few cases the vision is lost. Both eyes are rarely involved at the same time, but when panophthalmia is bilateral the second eye is involved within a few days of the first. There is photophobia, the eye is bathed in tears, these escaping in

paroxysms so to speak. The eye is sometimes tormented by distressing subjective symptoms, red or orange colored flashes or flames being seen, even when the eye is protected from the light. A yellow reflexion without pain appears in the papillary field; this is the vitreous humor beginning to suppurate, while at the same time a considerable palpebral edema appears which hinders examination of the globe. A gelatinous chemosis forms a ring around the cornea, the iris loses its color, assuming a cadaveric look, and the pupil becomes irregular in outline. The aqueous humor becomes cloudy, the anterior chamber diminishes in capacity and is soon invaded by epithelial detritus which forms hypopion. The latter is very mobile, fluid, with a pale yellowish green color. A sudden movement of the head mixes the hypopion with the aqueous humor, while by rest it quickly reforms. The cornea remains transparent. Opthalmoscopic examination is possible as long as the vitreous humor has not begun to suppurate. Retinal hemorrhage around the macula can be seen, also around the papilla. The hemorrhages are small, punctate, but numerous. The thickened retina lies in folds along the large vessels forming crests with a whitish reflection. Soon purulence of the iris occurs, the cornea becomes cloudy, its anterior surface loses its usual shiny look. At this time the formidable symptoms of phlegmon of the eye appear; intolerable pain in the globe and circumorbital region with glaucomatous tension.

Besides this form of panophthalmia there is another slower painless type, the so-called torpid form. In the type purulent from the onset the pain results from intraocular tension; in the torpid form the tension is absent because the vitreous humor has rather a tendency to retract. As an objective symptom there is a marked and rapid decline in vision. In this form the sight may be recovered, but never completely, because although the vitreous may become again transparent, it nevertheless contracts resulting in detachment of the retina so that light perception occurs only at the periphery, the ora serrata.

Metastatic panophthalmia should not be mistaken for any other form of ocular suppuration, and when a pus focus exists in the body it must be suspected. Phlebitis of the ophthalmic vein is differentiated from panophthalmia by the enormous exophthalmos—the most characteristic sign—and a more accentuated edema of the lids. Sometimes the phlebitis extends to the circumorbicular veins that can be felt like hard cords, and occasionally some purulent spots may be noted in the conjunctiva. A diagnosis will be made by finding a trifling furunculosis on the face or lips, or inflammation of the Meibomian veins may engender phlebitis of the ophthalmic vein which, when death does not occur from thrombosis of the cavernous sinus with cerebral abscess, ends in panophthalmia. The accentuated exophthalmos distinguishes phlegmon of the orbit, while tenonitis can be diagnosed by the difficulty in moving the eye, and this moreover rarely goes as far as suppuration.

The prognosis of metastatic panophthalmia is very serious and usually sight is lost, and even in the milder cases it is rare that any degree of visual acuity is preserved, though in extremely mild cases the vision may return to normal. The opinion is generally maintained that panophthalmia disorganizes the ciliary nerves to such an extent that it prevents the appearance of sympathetic accidents in the fellow eye. The prosthetic prognosis will be better in cases where exenteration, rather than enucleation, has been done, because the stump will be larger and in some cases will allow a certain mobility.

TREATMENT OF UTERINE INFECTION POST ABORTUM.

THE abuse of the curette in this condition makes it necessary to establish certain rules of procedure in which the curette may be indicated or contraindicated. Douay, who contributes an article on this subject in *Gynécologie et Obstétrique*, ii., 6, says that Vignes has recently advised against the use of the curette, save for the removal of placental fragments. Since the alternative must be curettage or hysterectomy it is well to ascertain if more latitude cannot be given for the lesser intervention. The old advice of Faure was to curette and watch for an indication to remove the uterus through the vagina, but to curette only on the belief in retained placental tissue. The maximum delay before hysterectomy is 48 hours. Douay, an old assistant of Faure, has seen the latter violate his own rule and abstain from both kinds of intervention—in one class of cases because there was a good chance of recovery by medical measures, and in the other because intervention could only hasten the end.

So far as rules can be laid down, Faure advised the sharp curette in the presence of slight infection for removal of placental débris. The slight infection, along with hemorrhage, was indeed one of the reasons for the intervention. Undertaken at a certain stage the operation was innocuous and brought prompt relief. The instrument in these cases could loosen the placental fragments without too serious advance into the mucosa. But if the infection had gotten beyond the limits of the mucosa the formation of a wide bleeding wound which laid open the vessels paved the way for infection. If one is called in to the case late, the state of the uterus is usually an index of the presence or absence of placental débris—a large, soft, globular organ with patent cervix showing retention. In such cases there is still the great advantage of evacuating the uterus; but if there is no evidence of retention the presence of symptoms of sepsis, as chills and fever, may or may not indicate a vaginal hysterectomy.

Douay would in doubtful cases always make preparations for hysterectomy and if, after examining the cavum, only a small amount of placental

débris was found would operate at once. But if there was a considerable amount which could be readily evacuated he advised delay, even to several days in some cases. Curettage of a severely infected uterus is a true operation and not a minor procedure. In such a case the dull must be substituted for the sharp curette. With this he would only detach the larger portions of placenta and then would irrigate with hot water (50° C.) and hydrogen peroxide. The curette is now used systematically—and finally, for no second attempt is ever justifiable. Another irrigation is practised and in very severe infection antiseptic gauze is left in the upper vagina, including the posterior cul-de-sac, for 24 hours to support the uterus and receive the secretions. If the abortion has occurred after the fourth month the sharp curette is not used, but a large blunt one, followed by intrauterine irrigation. A slight chill after curettage has no unfavorable prognostic significance. Later developments determine the question of after-treatment. A bacteriological examination may show that the offender is not the streptococcus, in which case medical measures may prove adequate. Hemoculture is of great service; if it is negative, one should hesitate about hysterectomy, while if positive the operation will probably not save the patient, although it is the only chance left for her. If it occurs before three months, infection *post abortum* is not a severe condition compared with the postpartum case.

Cruel Treatment of Drug Addicts.

THE New York City Board of Health adopted an amendment to the sanitary code a few days ago, permitting the incarceration of drug addicts, and immediately thereafter a police hunt for these poor creatures was started. The hunt was fairly successful, quite a bag of game being brought in. The victims were thrown into cells, and the usual result of sudden withdrawal was shown in the death of one man and the collapse of several others who had to be treated by ambulance surgeons. According to the newspaper reports Dr. Carleton Simon, special deputy police commissioner, denied that the death of one man and the collapse of the others were due to withdrawal of the drug, and is quoted as saying: "There is no record of any drug addict ever dying because of drug removal." It must be that Dr. Simon was misquoted for no man fit to occupy his position could possibly be so ignorant of the elementary facts of drug addiction. As a correspondent shows in a letter published in this issue of the MEDICAL RECORD, at least three acknowledged authorities on drug addiction, and he might have quoted others, make the unqualified assertion that death may and not infrequently does result from the sudden withdrawal of the drug. As, of course, Dr. Carleton Simon must be familiar with the literature of the subject, there can be no acceptable alternative to the belief that he was misquoted. But that being postulated, the fact that one prisoner died and others were in a serious state of collapse calls for explanation. Even admitting that 70 per cent. of drug addicts are criminals, which is another statement attributed, perhaps incorrectly, to Dr. Simon, the law does not permit their execution without trial, and whoever is responsible for this shocking inhumanity should be punished.

Fees.

QUITE a pother has been made in the newspapers over the announcement that the trustees of Johns Hopkins Hospital have made a rule governing the charges of surgeons and internists treating patients in the institution. The edict records that "The maximum fee that any surgeon ought to charge for an operation, no matter how wealthy the patient may be, is $1,000. The maximum charge that any physician ought to make for attending patients in a hospital is $35 a week." The dictum is in line with the increasing tendency toward lay control of medical practice, but it concerns only the physicians and surgeons at one particular hospital. The surgeons at the Peter Bent Brigham Hospital in Boston will not feel under any obligation to abide by this rule, neither will those at the Mayo Clinic in Rochester, Minn. Nor should it, nor will it, influence any other surgeon with self respect and a just appreciation of his own worth. Surgeons outside of the Johns Hopkins will continue to charge what they deem proper, whether fifty dollars or five thousand, and one thousand will not be their minimum, as it might be if the law restricted them to a maximum of this amount.

News of the Week.

Pellagra in the South.—The statement recently issued by Surgeon General Cumming, U. S. P. H. S., to the effect that a condition of semifamine exists in a large section of the "cotton belt" of the United States, and that there is thereby created great danger of an increase in pellagra, has been met with indignant denial by many health officers and others living in that part of the country. The Southern Commercial Congress called a public health conference to meet in Montgomery, Ala., Aug. 15. In the meantime, acting with the approval of President Harding, Surgeon General Cumming invited State health officers of thirteen Southern States to meet in Washington August 4 to consider the situation and to confirm or disprove the reports of a threatened pellagra epidemic in parts of the cotton belt. The Public Health Officers maintain that the data in their possession show that pellagra has increased as a result of economic conditions, and they insist that if a situation that may be much worse in 1922 is to be forestalled tenant farmers, factory workers, and others resident in the pellagra sections should be instructed as to what is necessary to prevent the disease.

Resolution of the New York Board of Health Regarding Drug Addiction.—At a meeting of the Board of Health of New York City, held July 25, 1921, the following amendment was added by resolution to the Sanitary Code:

Section 130. *Prohibited Acts Constituting a Public Menace.*—Any unauthorized possession, sale, distribution, prescribing, administration or dispensation of cocaine or opium or any of their derivatives, or cannabis indica, cannabis sativa, or any of

their derivatives, is hereby declared to be dangerous to the public health and a menace to the public welfare.

Section 131. *Prohibited Acts.*—It shall be unlawful for any person to possess, sell, distribute, administer, dispense or prescribe cocaine or opium or any of their derivatives, or cannabis indica, cannabis sativa, or any of their derivatives; provided, however, that nothing herein contained shall be deemed to prohibit the possession, selling, distributing, administering, dispensing or prescribing of any of the drugs or their derivatives as in this article hereinafter provided.

Section 132. *Authorized Acts of Trades and Professions.*—A manufacturer, wholesaler, apothecary, physician, dentist, veterinarian, private hospital, sanatorium or institution maintained or conducted in whole or in part for the treatment of disability or disease or inebriety or drug addiction, may purchase, receive, possess, sell, distribute, prescribe, administer or dispense cocaine or opium or their derivatives, or cannabis indica, cannabis sativa, or any of their derivatives, provided he shall have complied with all provisions as required by the Act of Congress of December seventeenth, nineteen hundred and fourteen, known as the Harrison Narcotic Law, as the same exists and may be amended.

Section 133. *Hypodermic Syringe.*—No person except a dealer in surgical instruments, apothecary, physician, dentist, veterinarian or nurse, attendant or interne of a hospital, sanatorium or institution in which persons are treated for disability or disease, shall at any time have or possess a hypodermic syringe or needle or any instrument or implement adapted for the use of cocaine or narcotic drugs by subcutaneus injections and which is possessed for that purpose unless such possession be authorized by the certificate of a physician issued within the period of one year prior thereto.

Section 134. *Exemptions.*—The provisions of this article restricting the possession of cocaine, opium or their derivatives, or cannabis indica, or cannabis sativa, shall not apply to common carriers or warehousemen or their employees engaged in lawful transportation or storage of such drugs, nor to public officers or employees while engaged in the performance of their official duties, nor to temporary incidental possession on the part of employees or agents of persons lawfully entitled to possession.

Section 135. *Commitment of Addicts; Procedure; Treatment; Discharge.*—The habitual use of cocaine, opium or their derivatives, except as administered, prescribed, or dispensed by a physician, is hereby declared to be dangerous to the public health and safety and in violation of this article. Upon the voluntary application of an addict, any Court or Magistrate, may, if satisfied of the truth thereof and that the person is suffering from such drug addiction, commit such person to a county or city hospital or institution maintained by the City of New York, or any correctional or charitable institution maintaining a hospital in which drug addiction is treated, maintained by the City, or any private hospital, sanatorium or institution authorized for the treatment of disease or inebriety. A Court or a Magistrate may likewise on voluntary application commit for treatment to any reformatory or correctional institution, maintaining a hospital or place where drug addiction may be treated, to which institution commitment could be made from the City of New York on conviction of a misdemeanor. Any court having jurisdiction of a defendant who is a prisoner in a criminal action or proceeding, if it appears that such defendant is an habitual user of any such drugs and is suffering as a result of such addiction, may, if it commit an addict making voluntary application, require the return to the Court of any such addict when such addict is cured or at a time stated in the order of commitment. Whenever the medical officer or superintendent or the head of such an institution shall certify to the committing Magistrate or Court that any person so committed has been sufficiently treated or give any other reason which is deemed by the Magistrate or Court to be adequate and sufficient, he may in accordance with the terms of commitment discharge the person so committed, or return such person to await further action of the Court, as above provided.

Section 136. *Fraud, Deceit, Et Cetera.*—Any fraud, deceit, misrepresentation, subterfuge, concealment of a material fact or the use of a false name or the giving of a false address in obtaining treatment in the course of which cocaine or opium or their derivatives shall be prescribed or dispensed or in obtaining any supply of such drugs shall constitute a violation of the provisions of this article and shall not be deemed a privileged communication. The wilful making of any false statement in any required prescription blank, order or record, shall constitute a violation of this article.

Section 137. *Penalties.*—A violation of any of the provisions of this article shall constitute a misdemeanor. The Department of Health shall by virtue of the authority conferred by the provisions of the Inferior Criminal Court Act of the City of New York as amended by Section 44, Chapter 531, of the Laws of 1915, except in a case where a commitment is made in the Magistrate's Court for treatment, request upon proceeding being had before a Magistrate that violations of this article be triable in the Court of Special Sessions, held by three Justices.

The previous sections dealing with habit forming drugs were annulled.

Poliomyelitis Shows Increase.—A special Bulletin of the New York State Health Department states that the number of cases of poliomyelitis reported to the State Health Department during the first twenty-seven days of July was twenty-five, a greater number than has been reported during any July since the epidemic of 1916, and an increase over the number of cases reported during the year. While the Department does not view present conditions with alarm, it has sent letters to health officers requesting them to be on the lookout for suspicious cases and offering the services of consulting diagnosticians in doubtful cases.

Drunkenness in England.—Drunkenness in England in 1920 increased 65 per cent. over 1919, but is still only a little over half the figures for 1913. The decrease in drunkenness began in the latter months of 1914 and continued during the war years and until the middle of 1918, when an increase was noticeable monthly, which continued through 1919. Encouraging signs are seen in the decrease which

began late in 1920. The highest figures are still far below the pre-war mark of 1913, which reached 188,000 convictions for drunkenness.

Red Cross Reports on Cancer Deaths.—The League of Red Cross Societies, which was asked to obtain all valuable statistics concerning the increase of cancer, has issued a report in which it states that in the four years from 1908 to 1912 cancer caused more than 1,500,000 deaths in the civilized countries. The report ventures the opinion that had people generally been better informed about the symptoms of cancer and been promptly treated at least 500,000 of these deaths might have been prevented. The country which had the highest cancer mortality between 1900 and 1919 was Switzerland with 125 per 100,000 inhabitants. Holland and England come next with about 100 deaths from cancer to every 100,000 population. Holland's cancer deaths are tending slightly to decrease. The United States comes after England with a steady tendency to increase. Italy comes last. The report of the League of Red Cross Societies pays generous tribute to the work of the American Society for the Control of Cancer, whose general conclusions on the subject of cancer it quotes.

Inadequate Care for Tuberculous Soldiers.—Dr. N. A. Pattison of New York, supervisor of the medical service of the National Tuberculosis Association, testifying recently before the Senate Committee on Soldiers' Relief, declared that the facilities for caring for ex-soldiers suffering from tuberculosis "are grossly inadequate." Dr. Pattison gave this opinion following a visit to fifty hospitals located in forty-four states. He points out that the Government to a large extent is utilizing old base hospitals constructed of flimsy material involving a terrific fire risk. He mentioned several hospitals which he said should be abandoned immediately. Complaints were lodged against certain hospitals which Surgeon General Cumming was called upon to investigate. Dr. Haven Emerson, assistant director of the War Risk Bureau, admitted failure on the part of the Government to provide proper inspection service for the hospitals, but insisted that insufficient appropriations were responsible.

Condition of Children of Pre-School Age in New York.—The *Weekly Bulletin* of the New York City Department of Health reports the results of a physical and mental examination of 1,061 prospective entrants of the New York public schools, examined in eight public schools of Manhattan during the month of June last. Of these 1,061 children, between the ages of five and six years, 33.3 per cent. were found normal and 66.7 per cent. showed physical defects. Of the children examined 72.6 per cent. had defective teeth. The other outstanding defects were hypertrophied tonsils, defective nasal breathing, and malnutrition. A higher percentage of these defects was found in this group of children of pre-school age than in children of school age. The study corroborates former experience as regards the need of intensive work among children of pre-school age, for the correction of remediable physical defects. It also emphasizes the fact that the public, as a whole, has not yet realized the importance and significance of the ill effect of physical defects at this age, and the importance of their remedy from the standpoint of health and schooling.

Appointments in the Bureau of Chemistry of the U. S. Department of Agriculture.—By an order of Secretary of Agriculture Wallace, Walter G. Campbell, assistant chief of the Bureau of Chemistry since 1916, is made acting chief to fill the place of Dr. Carl L. Alsberg, whose resignation became effective on July 15. Dr. W. W. Skinner, chief of the water and beverage laboratory of the bureau since 1908, is designated as assistant chief.

Dr. **Edmund L. Gross**, head of the American Hospital in Neuilly, France, has arrived in this country.

Dr. **W. C. Billings** of the United States Public Health Service has been appointed medical head of Ellis Island as director of medical inspection of immigrants to succeed Dr. J. W. Kerr, who has been transferred to the Surgeon General's office.

Obituary Notes.—Dr. CHRISTOPHER JAMES MUSGRAVE of New York City died at his home on July 28 at the age of fifty-six years. He was graduated from New York University Medical College in 1887. He was a member of the American Medical Association and formerly an instructor in the Post Graduate Medical College and Hospital.

Dr. CYRUS B. NEWTON of Stafford Springs, Conn., a graduate of Yale University School of Medicine in 1856, died in a local hospital on June 19, at the age of ninety years. He was a member of the American Medical Association, warden of the Connecticut State prison for a number of years, medical examiner for Tolland County in 1895, and a member of the medical board of Johnson Memorial Hospital.

Dr. WALTER RANDALL PIKE of St. George, Utah, died at his home on June 10, at the age of seventy-three years. He was graduated from the University of Vermont Medical College in 1877, was formerly superintendent of the State mental hospital, and in 1892 a member of the State Legislature.

Dr. JEHIEL W. CHAMBERLIN of St. Paul, Minn., died at his home on June 14, at the age of sixty-four years. He was graduated from Rush Medical College in 1882. He served as president of the Ramsey County Medical Society, the Minnesota Academy of Medicine, and the Minnesota Ophthalmological Society.

Dr. WILLIAM A. BELL of Colorado Springs, Col., a graduate of the University of Cambridge, England, died on June 7, at the age of eighty years. His name is closely linked with the early history and development of Colorado Springs. He was interested in the founding of the Denver and Rio Grande Railway system and was one of the founders of the Colorado Coal and Iron Company in 1879.

Dr. BELA J. WARD, a graduate of Albany Medical College in 1884, died at his home in Albany on June 28.

Dr. WARD E. HUNT of Little Falls, N. Y., died of diabetes in a Utica hospital on June 25, at the age of fifty-two. He was graduated from Albany Medical College in 1893, and was a former president of the Herkimer County Medical Society.

Dr. CHARLES O. SMITH of Atlanta, Ga., a graduate of Emory University School of Medicine, Atlanta, in 1892, died on June 30, at the age of fifty-six years.

Dr. JOHN T. ROBERTS of Beaumont, Texas, a graduate of the Southern Methodist University

Medical Department (Texas) in 1911, died on June 28, at the age of thirty-three years.

Dr. THOMAS T. EARLE of Greenville, S. C., a graduate of the George Washington Medical School in 1870, died at his home on June 29, at the age of seventy-six years.

Dr. HENRY J. DEHANN, a graduate of the Missouri Medical College, St. Louis, in 1884, died after a lingering illness on June 25, at the age of sixty-three years.

Dr. WILLIAM M. PARRY for many years a practitioner of medicine in Waynesburg, Pa., died after a long illness on June 25, at the age of seventy-eight years. He was a Civil War veteran and the oldest member of the Greene County Medical Society.

Dr. W. W. CULPEPPER of Athens, La., a graduate of Tulane University, and a Confederate veteran, died June 22, at the age of eighty-eight years. For a number of years he was college physician at Mt. Lebanon College.

Dr. JAMES E. GROFF died at Doylestown, Pa., on June 10 at the age of 65 years. He was graduated from Jefferson Medical College in the class of 1880. He was a member of the Bucks County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. HENRY BILLINGTON NIGHTINGALE died at Philadelphia on June 23 at the age of 66 years. He was graduated from Jefferson Medical College in the class of 1876.

Dr. ROBERT WESLEY JOHNSON of Assumption, Ill., a graduate of the Eclectic Medical College, Cincinnati, died on June 10, at the age of seventy-two years.

Correspondence.

THE SYMPOSIUM ON CALCIUM METABOLISM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: — The symposium on calcium metabolism, which was staged at the New York Academy of Medicine (March 3, 1921), an abstract of which appears in the MEDICAL RECORD, July 2, 1921, p. 39, presents some interesting and instructive data which should prove intensely interesting to physicians and members of the medical profession. For example, Prof. Rodney H. True discussed in technical terms the results of laboratory investigations relating to the functon of calcium in plant nutrition, while Prof. H. C. Sherman presented data relating to the calcium requirements in animal nutrition, and in his remarks referred especially to the recognized calcium deficiency in American diets. The general discussion following these addresses was not less interesting than the contributions themselves; Dr. Hess, Dr. Wallace, and Dr. Tweddell advancing various suggestions and records bearing upon the unfortunate results attending such deficiency of the inorganic proximate principles, and especially the deteriorating effects upon human nutrition.

It is evident, however, from a careful study of the entire abstract, that none of these gentlemen who took an active part is thoroughly familiar with the records covering experimental investigations, though there is scarcely room for criticism because of the fact that the question is so large, so far reaching, and the investigators have conducted their studies in so many different directions. Such being the case it will not seem presumptuous in me to add some further references bearing upon animal and plant nutrition, and at the same time indicate how these investigations dovetail and harmonize with our modern theories relating to calcium metabolism; so, instead of a criticism, this communication is intended for the purpose of elaborating and completing the various disconnected facts, scientific and clinical, which have a direct bearing upon the treatment of disease. Thus, I find no reference in Prof. True's remarks to indicate that he has considered the influence, either direct or indirect, immediate or remote, of mass action; nor does he intimate that there is such a chemical transformation which gives mineral substances, in minute subdivision, properties similar to, although not identical with, the enzymes—the unorganized ferments, that is to say, mineral ferments. Prof. Sherman's remarks refer to various experimental investigations conducted by physiological chemists, and is thoroughly commendable; according to his studies it is his impression that one in fourteen of the American public is trying to live on a diet deficient in calcium, but he doubts if the deficiency can be made up from drinking water. Prof. Sherman does not think that it would be wise or expedient to add calcium in any form to the ordinary diet, although this has been done to a limited extent by a well-known baking company in the manufacture of bread; he thinks it would be preferable that we "should encourage the more liberal use of foods, such as milk and vegetables, containing other mineral salts, which possess an all-around well-balanced mineral content and are important for their vitamines as well."

Evidently Prof. Sherman has a leaning toward the vitamines, but this position is scarcely warranted in view of the results obtained by Daniels and Loughlin (*Journal of Biological Chemistry*, November, 1920), in their study of the deficiency of heat-treated milk. The records of their investigations show clearly that the fat-soluble and water-soluble vitamines are not destroyed even by long boiling, although the milk thus treated fails to support life in the albino rat. That was the result of employing evaporated milk either in its natural condition or diluted, while on the other hand, dried milk, served or fed in its original form, maintained nutrition and secured reproduction. As a result of further investigations it was found that the inorganic or colloidal particles of the calcium, which properly belonged in the evaporated or diluted milk, were lost by reason of their adherence to the container or falling to the bottom of the vessel used in feeding. Long heated milk, however, is deficient in calcium because the latter is rendered inert. Presumably, it is in the form of an irreversible colloid, and as such is not to be depended upon to enact the rôle of a mineral ferment.

Mass action is rather a difficult problem to understand, but a brief reference to the subject will serve to aid us in working out a substantial and practical physiological basis in the employment of food materials. Prof. True makes the following statement, as reported in your notice of the meet-

ing: "The question of the calcium-magnesium ratio which had long been a subject of discussion among those interested in plant physiology had received over-emphasis. They had found little evidence that the calcium-magnesium ratio was as important as

LESTER D.—Age 20 months, weight 36 lbs.

some investigators had thought it to be. So long as calcium was present its ratio to the quantity of magnesium was of little significance. When mixtures of three salts were used it was found that these were nearly complete solutions for plant growth, provided calcium was present, indicating that the function of calcium was predominant, and that if other salts were present and calcium absent the plant structure fell apart."

In this connection we have a very instructive illustration, in fact a demonstration, of the exceedingly complex conditions with which we have to deal in human life. Thus, the report of the United States Department of Agriculture, on the soil of Porto Rico, shows that it is composed largely of alumina and silica, and that the soil is persistently acid, so that liming is absolutely necessary. Two tons of lime per acre is necessary to neutralize the acid, but this alone will not produce a crop, and at the end of a season an examination of the soil shows absolutely no lime present—an indication that mass action has taken place in the soil. In order to grow a crop upon that soil, it is necessary to add four tons of lime more to the acre, that is, in addition to the two tons required to neutralize the acid.

It frequently happens that physicians, and I am no exception, observe results attending medical treatment which are astonishing, to say the least, but I doubt that these notable effects can be established as permanent without proper attention to the dietary. The clinical evidences bearing upon mass action and mineral ferments is overwhelmingly in favor of colloidal medicaments, because, for the most part, medicines in order to be effective, must be converted into this form. The following cases are submitted tentatively to emphasize the remarks of Prof. True, and besides, his observations will relieve me in part, at least, of the charge of medical transcendentalism.

The first case is that of Lester D., age 21 months, weight 36 lbs. The first picture in the text shows the child at age of 20 months. Treatment in this case beginning at 21 months consisted in regulating the dietary and giving $2\frac{1}{2}$ grains of carbonate of calcium from oyster shell, three times a day for the period of one month. Improvement set in at once, but owing to the marked success which I had been meeting in the case of enuresis in children when giving the equivalent of one half grain colloidal calcium, this was the dose for the succeeding three months—thus, the treatment covered a period of four months. At the expiration of the four months, the dose of colloidal calcium was increased to the equivalent of two grains three times daily, and at the end of six months the second picture was taken, which shows remarkable improvement. The weight at this time was only one pound more than at 21 months, but the child had gained one inch in height.

Little comment is required in this case, except to say that the child was nursed until 11 months of age, at which time he was weaned and fed upon a well-known and popular baby food until he came under observation, and it was during this latter period that the bow legs developed, showing that there was some fault with the diet. Still, this baby food required the addition of cow's milk, and it seems there was no reason why the diet should have failed to produce normal nutrition. Apparently, all that was needed was the colloidal calcium, which acted as a mineral ferment and promoted, or stimulated, mass action in the inorganic proximate principles.

Another case is that of Ann, 7 years of age, a "backward" child. The mother said Ann was dumb, and she looked it. She could not, or would not, talk; she objected to going to school and either could not or would

LESTER D.—Age 27 months, weight 37 lbs., height 37 inches.

not learn. There were seven children in the family, the oldest 11 years, and although the parents were healthy and robust, and all the other children apparently were in normal condition, they had given up hopes of being able to make anything of Ann—and besides, they were in poor financial circumstances and

there was no question about the dietary deficiency. Another feature, and the principal one for which I was consulted, was bed-wetting—this had been persistent for several years and had resisted the most earnest solicitation of several physicians. Treatment consisted in giving the equivalent of two grains colloidal calcium after meals, the dietary to be properly regulated; milk for breakfast was insisted upon, no fruit such as apples or oranges, allowed after the midday meal, and no water to drink was permitted to be given after the evening meal. As a result of this regime, bed-wetting was stopped immediately, and three weeks later the child got 100 in spelling at school. She improved in every way and in the course of a few months her mother said she was the brightest child in the whole family.

Another case worthy of mention is an Argonne gas victim. The history of the case runs about as follows:

B. D. M., age 28, weight 160, now a student, was gassed in the Argonne advance, and has been under treatment ever since he returned from France, under the direction of the medical board which made a liberal debility allowance, although the medical attendants to whom he was sent from time to time, insisted that he was a malingerer. He complained of constant headache, so severe that he was unable to sleep, although he tells me that the sinuses, including the antrum, have been irrigated at least forty times during the past year and a half. This patient came under observation May 25 ult., and returned June 2, at which time he reported that his headache had entirely disappeared, that he was unable to get a sufficient amount of sleep, said he had slept nearly all day Decoration day; said he was feeling fine and that he was now able to concentrate his mind on his studies and expected to make rapid progress. Treatment in this case consisted in the administration of colloidal calcium, the equivalent of two grains after meals, and at bed-hour, as the basic or dominant treatment, the collateral treatment being 1 17 grain potassium bichromate in the form of two tablet triturates, to be taken before meals and at bed-hour.

I cannot close this communication without a brief reference to the function of calcium in animal nutrition, as developed by W. P. Wheeler, First Assistant (Animal Industry), embraced in Bulletin 46, New York Agricultural Experiment Station, December, 1919. The experimental observations were conducted with fowls (chickens) usually in lots of six, also with ducks, and the inorganic principles studied were limited to calcium, strontium, and magnesium. Omitting reference to the dietary deficiency among ducks, and the comparable effects of strontium, I will attempt to epitomize the results of these investigations which covered a considerable period of time, and embraced many interesting and instructive tests in the course of the investigation. Briefly stated, the results are as follows: When two lots of chickens were fed the usual dietary and one of these lots received calcium in addition, this second lot laid three or four times as many eggs as the former. When the chickens were limited to a dietary carrying a deficiency in the lime content, it was found that the lime in the egg-shells was greater than in the food. And finally when the chickens were fed on a diet containing a deficiency of lime and an excess of magnesium, the results were extremely unsatisfactory, as the following extract shows: "In the matter of influence on egg production, the results, on the whole, plainly favored the rations with the large proportion of calcium. Under the unusual rations free laying could not be expected, but three and four times as many eggs were obtained from hens fed the added calcium as from other lots. Fewer eggs were obtained from the hens fed added magnesium salts than from the hens fed strontium salts. With the younger hens, from which readier egg production would normally be expected, laying started earlier and continued longer with the lot fed calcium salts."

A pertinent and *suggestive* report, showing the injurious effects of calcium deficiency upon reproduction, is presented by Drs. Reynolds and Macomber, of Boston, Mass. (*Jour. A. M. A.*, July 16 1921, p. 171). Briefly stated, the record is as follows: "The wife was a large, well-nourished woman in ordinarily good health, but reported herself as lacking in energy and constantly tired. . . ." During the seven years of married life one child was delivered at full term at the expiration of ten months, but died during operative extraction; then followed five early miscarriages in six years, when a survey showed she had been living on a diet deficient in calcium. This was corrected by the medicinal administration of calcium, the diet being arranged to include foods rich in calcium—with the result stated: "She went into her seventh pregnancy shortly afterward and without any other treatment was delivered at term of a healthy child."

NOBLESSE OBLIGE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—To the question of the proper amount of surgical and medical fees there is one very simple answer, and this every man of character applies to himself in his doings with others.

No man has a right to lower his well earned reputation by doing what does not befit it. To overcharge is, also, simply a lowering of a great and noble calling. Woe sooner or later comes to the man who condescends to do for mere lucre what should be done for humanity. Such action sadly neutralizes before the public much that he has previously done to ennoble his profession. The men whom we most admire never charge exorbitant fees. They could do it and be paid, but they think of their peers in surgery and medicine and will not.

Again and finally, "noblesse oblige."

BEVERLEY ROBINSON, M.D.

NEW YORK.

THE FATAL RESULTS OF THE SUDDEN WITHDRAWAL OF OPIATES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Officials connected with the narcotic squad of this city are quoted in the press as making certain statements in extenuation of the sudden death of Otto Thompson, an opiate addict, who was found dead in a police station after arrest as a drug addict. One of these statements is that "drug cure records show no instance of a man dying because of drug removal." According to other reports his death was attributed to the heat. The fact seems to be, however, that the man was deprived of his opiate drug and died.

The medical literature on addiction to opiates gives so many instances of death resulting from the removal of the opiate that the acceptance of such a

possibility ought to be axiomatic with anybody at all familiar with the subject. Practically every writer of any importance on this subject refers to it. Merely to quote from three of the best known writers on the subject of narcotics and addiction (italics mine):

Dr. Alexander Lambert, in Osler's "System of Medicine," page 215, writes:

When morphine is cut off abruptly there is great danger of collapse. This may supervene on the second or third day and the patient shows increased weakness, appears pinched and haggard, while the pulse becomes small and then disappears. Or he may show a sudden high pulse tension, feebleness of the heart action and suddenly fall pulseless to the floor. Sometimes the fatal collapse may occur without warning while the patient is quietly talking or sitting in bed. Still another form of collapse may occur; the face becomes deep red, the eyes shine brightly, the pulse falls to forty and the patient loses consciousness after a feeling of intense agony. These collapses may last for fifteen or twenty minutes; they may recur three or four times in the twenty-four hours, and the patient may recover or *he may die in any of them unless morphia be given.* Fortunately these attacks are rare when the drug is withdrawn gradually, but *they are fairly common when this is done abruptly.*

Dr. Ernest S. Bishop, in his book, "The Narcotic Drug Problem," page 35, writes:

In observing opiate addicts over a length of time no one can escape the recognition of a chain of constantly present physical manifestations, inevitably following the non-administration of the drug of addiction. . . . In a general way they may be said to begin with a vague uneasiness and restlessness and sense of depression; followed by yawning, sneezing, excessive mucous secretion, sweating, nausea, uncontrolled vomiting and purging, twitching and jerking, intense cramps and pains, abdominal distress, *marked circulatory and cardiac insufficiency and irregularity,* pulse going from extremes of slowness to extremes of rapidity with loss of tone, faces drawn and haggard, pallor deepening to greyness, exhaustion, collapse, and *in some cases death.*

Dr. George E. Pettey, in his book, "Narcotic Drug Diseases and Allied Ailments," page 41, says:

The abrupt withdrawal of an opiate from patients addicted to its use without first preparing the patient's system for such withdrawal *is not only dangerous to life but is barbarous.* This course is not now pursued in any reputable institution for treatment, but it is often practised in our insane hospitals and jails. Persons who are addicted to narcotic drugs are arrested, thrown into a cell, without any provisions whatever to supply them with the drug, and within twenty-four to forty-eight hours *the victim is taken from his cell a corpse,* having sunk into complete collapse. He was already *in extremis* when arrested, and being thrown into a cell where he is helpless and unprotected he soon sinks into collapse *and death closes the scene.*

This whole muddled narcotic drug situation has developed in the last two years because the laity and the officials have not been properly instructed by those whose business it is to know the facts and educate concerning them.

NEW YORK.

STILL OUT OF STEP WITH JIM.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—May I express through your columns my thanks to Dr. J. Milton Mabbott for his letter in your current issue, July 30, in which he so kindly and ably, though perhaps unconsciously, supports and gives confirmation to the material in my letter, published in your issue of July 23, concerning Dr. Alfred C. Prentice and entitled "All Out of Step with Jim."

ERNEST S. BISHOP, M.D.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, July 4, 1921.

Health Congress.—On June 20 last a Congress concerned with health matters under the auspices of the Royal Sanitary Institute of Great Britain was opened in Folkestone and continued for three days. Among the many subjects of interest discussed was that of alcohol. Dr. Courtenay C. Weeks quoted the National Insurance Commissioners as saying that there was lost annually through sickness and disability among insured people the equivalent of fourteen million weeks' work. It was further pointed out that in our asylums we had 125,000 lunatics and 150,000 feeble-minded persons, and the chief medical officer of the Ministry said that if the deficiency in the national life was to be met the first thing they had to deal with was alcohol.

In the section devoted to industrial hygiene an excellent presidential address was made by Viscount Burnham, who said that in the Victorian era it would have been considered an interference with Divine Providence as well as with individual liberty to have attempted anything in the direction of industrial hygiene. The Manchester School of Economists would have thought of this as mollycoddling, or what would be termed nowadays spoon-feeding. It was not want of humanity, but difference of view that caused them to take this line of policy. On the other hand, it was possible too great advance was being made in the other direction, and certainly due safeguards were required to prevent the national character from being enervated and even emasculated by too much supervision and interference. In America welfare work, if imposed by authority in the works, factories and mills, was resented as being paternalism, and in what was done in connection with industrial hygiene in Great Britain, it was essential that there should not be the spirit of paternalism, but the spirit of co-partnership. Unless there was a concordat between employers and employed it would be found that the great difficulty lay not in the material facts, though they might be stubborn enough, but in the veiled hostility, or at best indifference of the working people to their own welfare. It was essential that there should be a free and frank alliance, not only in aim but in practice, between employers and employed. Unless there was that cooperation of energy and goodwill the progress of social reform would be slow.

Sir Leslie Mackenzie, in his presidential address to the Sanitary Science and Preventive Medicine Section, said the new objective in preventive medicine was the production of fitness. This was one primary lesson of the war. There was no more illuminating study in the whole range of public health than the special investigation made during the war on industrial fatigue, bringing out just how the home of labor, types of food, character of the work, and the general conditions of the

factory showed themselves in the form of increased or diminished output as the case might be. The drift of the past thirty years had been from the study of environment to the study of individuals, and in medicine generally the drift had been from the study of the end products called disease to the incipient physiological deviations that need never become pathological.

Dr. D. R. Wilson, secretary of the Industrial Fatigue Research Board, summarized the results of the board's investigations on the effects of environment on output. In heavy work involving exposure to high temperatures, production, he said, underwent a consistent seasonal variation, being, with few exceptions, greater in winter than in summer, and the opposite effect was suggested in light work, such as silk weaving. Good ventilation was found to neutralize seasonal variations, and was reflected in the evenness of output throughout the year. In silk weaving it was estimated that even good artificial light caused a reduction of 10 per cent. compared with daylight.

Mr. G. L. Martyn Lobb, in dealing with the hospital as the primary health center in relation to a health service, referred to the motto of the New York State Department of Health that "Public health is purchasable," and went on to say that this was precisely so and there was the rub. Given unlimited money, an adequate health service would be a comparatively easy affair, but today money was anything but unlimited. It would seem that the great renaissance of medicine which we were witnessing could hardly have occurred at a more inopportune moment. The hospitals were complaining that they could not bear their present burdens, still less dare they add to them; and municipal authorities and the public, and the ratepayers, while applauding the abstract idea of primary health centers, dismissed it as a fantastic mirage, and cried, "Not one penny from us." The practitioners viewed the scheme as an insidious attempt of socialistic dreamers to rob them of the little they yet might earn. With regard to the hospitals he maintained that better organization would relieve much of the pressure of crowded premises and waiting lists. He hoped that the day of a sliding scale of payment for patients to a hospital was not far distant. Dr. Wheatley, medical officer of health for Shropshire, said he looked forward to a district nursing service trained in public health as a means of having a great number of cases now treated in hospitals dealt with at home. Another abuse was that too many treatments were being given in hospitals which could just as well be carried out in the patients' homes, or primary center, or convalescent home. It was time that a sort of "Doomsday Book" of England's convalescent accommodation was compiled, and that to every hospital, according to its size, a fraction of the available convalescent bed accommodation should be assured. Poor-law infirmaries were largely empty and if the stigma of pauperism were removed from the name their doors might be thrown open to the hospitals for convalescent patients.

Dangers of Anthrax From Infected Shaving Brushes.—As the result of a further investigation the Home Office Departmental Committee on Anthrax report that it has been clearly demonstrated that the process devised for the disinfection of wool is efficient as a method of disinfection of horsehair and that it can be satisfactorily applied without causing manufacturing difficulties. Certain modifications are necessary in the case of tail hair, but these are simply due to manufacturing necessities, and not to defects in the process. The committee are therefore unanimous in advising that this process is suitable for adoption as a method for the compulsory disinfection of horsehair. They have considered whether they should make any further specific recommendations, but see no reason for modifying the carefully considered proposals contained in the report on anthrax, which are equally applicable to wool and horsehair. Questions of detail ought to be dealt with by the authority which the report recommends should be set up with powers and facilities for enforcing disinfection of wool and hair. The report says as follows: "The fact has, however, been brought to our notice that large quantities of drawn hair, *i.e.* partly manufactured hair, are now being imported from China, and further, that consignments of shaving brushes made from infected hair are arriving in this country. The preparation of horsehair in China has now become established, and the trade in hair partly manufactured in that country is likely to increase at the expense of the raw hair trade. The satisfactory disinfection of such prepared hair and of shaving brushes is impracticable, while the danger to consumers is very great. Two courses only are possible, namely, (1) total prohibition of the import into this country of any manufactured or partly manufactured hair, and of goods composed or partly composed of foreign horse or goat hair; or (2) the establishment, in the countries from which such goods are imported, of disinfecting stations under the control of a central authority invested with the power to enforce disinfection of the raw hair before manufacture.

Malaria in the British Garrison of India.—In the report of the Sanitary Commissioner with the Government of India for 1920, issued recently, it is stated, that in spite of the prevalence of influenza, malaria retained its position as the chief cause of sickness and inefficiency among British troops in India in 1918. The admissions numbered 23,687, equal to 26.13 per cent. of the total admissions for all causes, and were in a ratio of 269.2 per 1,000 of total strength, as compared with 227.9 in 1917, and 117.2 in the pre-war Quinquennium 1910-14. It is pointed out, however, that the total admissions for malaria have probably been increased during each year of the war by the inclusion of relapse cases, whose infections were contracted overseas, and whose statistics should more correctly be debited against the Expeditionary Forces. Various drainage works were carried out, and it is stated that the "comparative absence of fresh infection during the latter half of the year is promising," in spite of the increased rainfall.

Bequest to the Royal Society of Medicine.—The late Sir Felix Semon bequeathed the whole of his laryngological library, except copies of his own writings, to the Royal Society of Medicine.

4. A Questionnaire on Sacroiliac Joint Lesions.—H. W. Marshall believes the time has come to sift the large amount of literature and clarify our ideas on certain subjects. One of these subjects is sacroiliac joint lesions. He has, therefore, collected a fairly comprehensive outline of ideas relating to this subject, ranging from reliable facts to plausible theories, and for convenient reference has arranged them in the form of a questionnaire, consisting of 80 questions. Copies of this were sent to a list of 350 selected physicians in the hope that they might assist in checking off such items as each could agree to personally, and thus aid in simplifying the present knowledge in reference to sacroiliac lesions. The replies furnish an interesting example of prevailing medical opinion and to what extent present orthopedic views are held by other departments of medicine. Emphasis is laid on the importance of understanding the physiological properties of the ligamentous and fibroid tissues of the sacroiliac and other joints and the opinion ventured that many treatments are being badly managed, and that more harm than benefit results from the medical care of back troubles, not infrequently because physicians reject unfamiliar ideas as unwarrantable theories. Backs, in consequence, may be supported too much, exercised too much, manipulated too vigorously, vascularizations neglected, and so on, and yet patients continue to recover, in spite of such treatment. Obscure vascular conditions and the way joints may be influenced through the blood are items about which the majority of physicians have rightly expressed doubts, although more might with advantage accept them as plausible theories. Eighty-two replies to the 80 questions are analyzed. No single item was unanimously agreed upon, though the majority of all opinions were agreed upon the majority of items. After reviewing all the ideas and opinions expressed, the writer thinks it easier to picture what determines the precise treatment any selected patient may receive. Treatments are determined, he finds, by clinical judgments carefully or hurriedly made, based on complete or incomplete understandings of underlying scientific facts and modified by clinical facilities at hand. He thinks it appears plain that any lightly conceived whim, perhaps erroneous, can decide what shall happen to the patient, despite all scientific safeguards.

3. Proofs of the Constitutional Nature of Cancer.—L. Duncan Bulkley points out that during the past one hundred years Abernethy, Walshe, Sir Astley Cooper, Sir James Paget, Dr. Willard Parker, Dr. Forbes Ross, Robert Bell, and others have expressed the belief that cancer is a constitutional disease. All the evidence in support of this belief has been disregarded by the medical profession at large, and surgery is regarded as the only hope for cancer, in spite of the demonstration that under its rule the mortality from cancer has risen steadily, since 1900 nearly 30 per cent. The reasons for the lamentable condition in which carcinosis as a disease stands today, in regard to its treatment and ultimate results, are not difficult to discover. They are: 1. The glamour of surgery and latterly of *x*-rays and radium, and the craze for immediate and spectacular results. 2. The claims of the surgeons as to the success of operation, and the failure to record and report end results, after the lapse of years. 3. The results of laboratory and research work, wrongly supporting surgeons as to the local nature of carcinosis, and advocating the desirability of the immediate removal of the results or products of it, now called cancer. 4. Ignorance on the part of the general medical profession as to the true facts concerning cancer. 5. The many fake cancer cures that have been foisted on innocent sufferers, together with the many failures of remedies and measures which have been advocated by the regular medical profession. The facts which point unerringly to the proof of the constitutional nature of cancer are presented in tabular form:

I. Laboratory Findings	Negative	Cancer is not parasitic. Cancer is not contagious or infectious. No cause for cancer has been found.
	Positive	Cancer cells are but altered normal cells. Feeding experiments show a possible control of cancer growth.
II. Statistical Evidence		Contrast of death rate since 1900 between cancer and tuberculosis. Steady increase of cancer deaths under active surgery, *x*-rays and radium.
III. Biochemical Evidence		Blood changes in early and late cancer. Metabolic changes in the system before and after the development of the local cancerous lesion.
IV. Clinical Evidence		Opinion of many celebrated surgeons during the last one hundred years to the present time. Spontaneous cures of cancer well authenticated. Dozens of hundreds of attested cases of benefit or cure of cancer by other than local measures, in this and other countries.

Most of the items in this chart are thoroughly known and accepted. Looked at in its entirety, the total evidence of the constitutional nature of cancer is fairly convincing.

4. Neuralgias of the Superior and Inferior Maxillary Branches of the Fifth Nerve Caused by Dental Pulp Nodules.—N. Philip Norman and Howard M. Johnston state that when diagnostic technique has been exhausted in the attempt to ferret out the cause of a trigeminal neuralgia, it is well to turn one's attention to the teeth, in order to exclude the presence of calcified pulp nodules. Such nodules may be present in apparently perfectly healthy teeth and can only be detected by careful radiographic examination of all the teeth. There is no definite relation between the presence of pulp nodules and the production of symptoms. At times such nodules may be present and do no harm. Having determined the affected tooth or teeth that is causing the pain, devitalization of the affected pulp nodules is the only treatment after the local and constitutional manifestations have failed. Two cases of severe trifacial neuralgia cured by devitalization and removal of a pulp nodule are reported. So far as the writers can find out, two such cases have never been reported before. The authors ask for the cooperation of dentists and neurologists throughout the country in gathering information in reference to the production of trifacial neuralgia by pulp nodules.

7. Needed Measures for the Prevention of Deafness in Early Life.—Harold M. Hays asserts that too much attention has been paid to the acute otologic conditions of childhood and too little attention has been paid to the chronic otologic conditions or, at least, to the causative factors which bring about deafness in later life. Most writers who have studied the subject carefully state that the majority of cases of acquired deafness are the result of neglect of the ears after measles, scarlet fever, and meningitis. The ears of the children are well taken care of during the acute stage of the disease, but frequently there is a residual process left or there is a continuation of the catarrhal process which forms part of the disease. Every parent who takes from the hospital a child who has suffered from one of these contagious diseases should be advised to consult an ear specialist at once, and, if there is the slightest impairment of hearing, every care should be taken to bring it to normal as soon as possible. There is sufficient data on hand in our histories of progressively deafened patients to realize that something more should be done for these cases than is do[illegible] present. Parents, teachers, and physicians should be educated as to the factors which give rise to deafness. Routine examination of children's ears in school must, in time, become as important as the examination of their eyes and teeth, and clinics must be established in the schools themselves, so that, under competent aurists, the treatment can be expedited. If we glance over the causative factors of deafness in adult life, we find that invariably there is a causative factor in childhood. Some of these problems can be dealt with very simply in childhood, but, if neglected, become most difficult problems after the child has reached the age of puberty.

11. Whole Blood Transfusion and Citrated Blood Transfusion.—Bertram M. Bernheim believes that the time has come when we should compare different methods of blood transfusion and possibly, in the application of methods, make a differentiation of cases. Inasmuch as we may expect a reaction in from 20 to 40 per cent. of all citrate transfusions, an attempt should be made to sift those cases which would seem to run a fatal risk if a reaction occurred, and give them the benefit of the more refined whole blood transfusion in which the percentage of reactions is hardly so much as 5 per cent. There are two groups of cases which, in the writer's experience, should not be given the citrated blood, namely: 1. Those in which there has been a hemorrhage of such intensity that the extreme limits of bleeding have been reached, and the patient is in such a state of shock that everything in the nature of additional shock must at all hazards be avoided. 2. Those states of anemia, either primary or secondary, in which the blood depletion has progressed to such limits that the patient is almost dead. As time progresses further differentiation will probably be made. Bernheim does not wish to be understood as belittling the value of citrate transfusion, but thinks it necessary to recognize that there are definite limitations to this method and that failure to observe these limitations has caused unnecessary loss of life. It is unfortunate that the giving of whole blood requires a far higher degree of surgical skill than does the giving of citrated blood; therefore, it seems that this method must always remain in the hands of the surgeon. There should be in every community at least one man who is competent to carry out the whole blood method, and physicians should learn to differentiate their cases so as to take advantage of this one man's skill.

13. The Psychic Factor in Exophthalmic Goiter.—Israel Bram contends that the syndrome to which we apply the term exophthalmic goiter is not goiter, and the sooner this affection is removed from the classification of goiter, the sooner will a rationalization of therapeusis be effected. While non-toxic goiter and toxic adenoma are local conditions yielding satisfactorily to thyroidectomy, this cannot be said of exophthalmic goiter, the etiology, and especially the symptomatology, of which is as widespread as the body itself. Every organ and its function, every tissue, every cell of the patient is involved; and when thyroid swelling exists, it is not the cause of but incident to or a link in the chain of events constituting the syndrome. Hence it is that in patients whose thyroids are not productive of marked pressure symptoms, whose vital organs are not too badly damaged, who are not insane, and in whom satisfactory cooperation is obtainable, the experienced individualizing internist obtains an excellent statistical showing. With the removal of any discoverable infectious foci, a properly outlined regimen of rest, diet, drugs, and other measures, and a practical psychotherapy pervading the whole, there is a correction of physical and mental vicious circles and a restoration of emotional and endocrine balance; and this, without added shock, without scars, with almost no recurrences nor mortality rate.

2. The Feces in Alimentary Disorders.—Robert Coope insists that the examination of feces must be integrated with the clinical findings, usually with a thorough examination of the urine, sometimes also of the blood. Not infrequently it provides data which the clinician finds very valuable in making his diagnosis. If foodstuffs occur in the feces in any notable amount, there is something abnormal, and this abnormality may be due to one of three things, viz.: (a) failure of digestion somewhere; (b) failure of absorption, or (c) hurrying on of the food so that there is not time for proper digestion or absorption. The abnormal findings can be divided into two categories: (a) absence of normal constituents; (b) presence of abnormal constituents. In the first category comes stercobilin. If stercobilin is absent one may safely draw the deduction that bile is not reaching the intestine. There is, unfortunately, no accurate quantitative method for estimation of stercobilin; however, when it is present by using a uniform technique, a rough idea may be obtained as to whether there is much less than normal In the second category are certain food residues—blood, soluble albumin, and mucus. For detecting soluble albumin the mercury perchloride test is used. Blood must be looked for on a controlled diet, and the writer generally uses the Weber guaiacum test. If trouble is suspected in the large intestine, it is often useful to

wash out with normal saline a short time after passing a stool, and examine the contents of the wash-out chemically both for blood and for soluble albumin, and, after centrifugalizing, examine the deposit microscopically. The significance of some abnormal findings in the feces is discussed.

4. Lymphadenoma and Tuberculosis.—I. Fox observes that many cases have been described in which tubercle bacilli have been found in the lesions of Hodgkin's disease. Generally these cases have shown locally a definite tuberculous lesion, clearly distinguishable from the lymphadenomatous process and often also from the appearance given by tuberculosis in organs not affected by lymphadenoma. In the case reported no gross tuberculous lesion was found postmortem, the only macroscopic changes being those of Hodgkin's disease of abdominal type. In the affected glands and spleen tubercle bacilli were found in fairly large numbers, and there was also in the spleen a focus of tuberculous type, but not very characteristic, which showed some resemblance to lymphadenoma. The vascular condition present might have been due to either disease. If this case were described as one of Hodgkin's disease, then, according to current theory, the tuberculosis was a secondary infection. Tuberculosis terminates many cachectic conditions, but does not, as a rule, select the tissue which is the chief site of the primary disease. In this case, since the abdominal glands of an adult were affected, the selection was more apparent than it would have been in a case of cervical or mediastinal lymphadenoma with tuberculosis. The obvious tuberculosis found postmortem in cases of Hodgkin's disease may have more significance than appears. One cannot but believe in this case that if the man's blood examination had not been so acute, he must have died before long of generalized tuberculosis. If he had the abdominal glands and spleen would hardly have been regarded as the original stronghold of the tubercle bacilli. It seems just possible that in deciding against a connection between the tubercle bacillus and lymphadenoma too much emphasis has been placed on negative results of inoculation experiments. But even if we admit that a true lymphadenoma, not caused by the tubercle bacilli, exists, it may well be that the term at present is applied to more than one disease, perhaps including a primary tuberculosis.

6. A Case of Placenta Prævia Centralis with Spontaneous Delivery of the Child. Alexander C. Blair.

2. On Chronic Nasopharyngeal Infection, Chronic Toxemia, and Distressed Heart in Children.—C. Paget Lapage calls attention to the following facts: 1. That chronic infection of the nasopharynx serves as one of the most important foci from which organisms may generate toxins which cause a chronic lowered state of health in the child. 2. That nasopharyngeal infection may be due to different kinds of organisms, the influenza bacillus being an especially potent factor and often acting as the initial infecting agent, though it may not remain in the nasopharynx. 3. That this toxemia often gives rise to heart lesions, and that, though these heart lesions may be valvular, they are often of quite a different nature from valvular lesions—that is, they are more in the nature of nervous irritation than of inflammatory troubles affecting the heart. That these special forms of heart trouble need methods of diagnosis which are not usually employed, while they also need different treatment from that usually prescribed. Before diagnosing toxemia following nasopharyngeal infection other conditions and toxemias must be carefully excluded. The symptoms of breathlessness, pallor, and chronic lassitude may be common to both infective and noninfective cases. These same symptoms may be produced by bad hygienic conditions, underfeeding, lack of sleep, and mental stress. A few days' rest in bed, when the condition is due to these causes, results in great improvement and serves to differentiate these cases from those due to infection. In the infective cases, removal of obstruction, if it be present, attention to the nasopharyngeal toilet, and proper physical exercise and drill have proved of great benefit. In other words, some cases of irritable heart disease in children should be treated by exercise and not by rest. The *x*-ray is often useful in differentiating the dilated from the nondilated heart and in determining whether rest or exercise is the appropriate treatment.

4. Results of Institutional Treatment in Surgical Tuberculosis.—E. D. Telford presents a report of the results obtained by him in the treatment of children crippled by tuberculosis at the Manchester Residential Schools for Crippled Children over the period of 1905-1918. An examination of the after-history of 159 cases discharged from the school not less than three years ago shows that 37 cases have died, two of accident. The figures show that of 100 children between the ages of five and sixteen years, treated under good conditions for tuberculosis of the spine and lower extremities, largely on conservative lines, 68 will be cured and able to attend an ordinary school or follow a useful employment; 10 will receive no permanent benefit, and 22 will die of the disease or its sequelæ. The very grave nature of tuberculosis of the spine is shown by the figures; of 70 patients with this form of tuberculosis 26 are dead. The mortality is much less for disease of the hip; nine out of 52. The knee shows only two deaths out of 31 cases. The development of abscess is always of grave omen. A comparison of these figures with those of institutions farther south makes it apparent that the farther north one goes the more virulent does surgical tuberculosis become. The average time needed for the treatment of these cases is considerably longer than is generally supposed. For example, in the writer's cases of surgical tuberculosis of the spine and of the lower extremities the average duration of in-patient treatment has been three years and two months.

2. An Important Step in the Technique of Cholecystectomy.—Murry N. Hadley stresses the point that the greatest single danger in cholecystectomy in the uncomplicated interval case is hemorrhage. This hemorrhage may occur from two sources—from the slipping of the ligature of the cystic artery, and from the traumatized inferior surface of the lobe of the liver from which the gallbladder has been detached. This latter source constitutes the greatest danger. A secure ligature can be placed on the cystic artery with every confidence that it will remain and prevent hemorrhage. Hemorrhage from the denuded under-surface of the liver can neither be prevented nor controlled by ligature. This hemorrhage is a venous ooze from the raw surface of the liver coming from injured biliary veins. It may not occur at the time of operation, the gallbladder bed appearing dry immediately following removal. The only way to insure the prevention of this kind of hemorrhage is to prevent actual injury to the liver substance. To accomplish this, one must remove the gallbladder in such a way that the liver is not traumatized. This can be done by making the incision which encircles the gallbladder attachments through its peritoneal and muscular coats down to the mucosa. The line of dissection should aim to leave as much of the gallbladder wall attached to the liver as possible. As the blood supply of the gallbladder wall comes from the cystic artery, ligature of this artery will control all hemorrhage if the line of dissection is made as above described. The structure of the liver is not entered and hence no hemorrhage will occur from its surface.

Book Reviews.

TEETH AND HEALTH: HOW TO LENGTHEN LIFE AND INCREASE HAPPINESS BY PROPER CARE. By THOMAS J. RYAN, D.D.S., and EDWIN F. BOWERS, M.D. New York and London: G. P. Putnam's Sons; the Knickerbocker Press, 1921.

A MIGHTY interesting subject is this, written in a snappy, up-to-date style which holds the attention of the reader and before he realizes it he is well into the middle of the book. The combination of authors assures this interest, for Doctor Bowers has written quite extensively on preventive medicine, especially for the laity, until he has literally drummed health and its advantages into the ears of a heedless world. Doctor Ryan, in no uncertain terms, has given sufficient knowledge of teeth and their relation to health and disease to more than startle Doctor Bowers' already prepared public.

One might be tempted to say that while this book is the last word in popular medicine, it has one of the glaring faults of so many books of today. It is too full of knowledge which is not sufficiently worked out in detail. Just as one becomes interested in a particular thought, or argument, Whisk! Presto! The big black headline of a new paragraph containing another point or argument is presented and one's mind has to perform a circus tumble to keep up with the rapid-firing change of topics.

After having read the book, the feeling of having been rushed through the subject-matter of dentistry, *Streptococcus viridans* and the frightful harm it can do, mouth washes, chewing gum, crooked teeth, twisted brains, the real meaning of teeth, etc., is full upon the reader. A quick-drawn breath, a pause for air, the book is put down, and if the reader does not rush off to the nearest dentist, wild-eyed, with all the primitive in him (or her) demanding truth, then it will not be because the authors have not done their best to impress upon him the importance of his dental health and the dire results of not possessing thirty-two immaculate teeth. The book is practical, fairly scientific and enjoyable, but like most things in life needs a big dose of commonsense to be taken along with the reading.

DER GYNÄKOLOGISCHE OPERATIONSKURSUS. Mit besonderer Berücksichtigung der Operations—Anatomie, der Operations—Pathologie, der Operations—Bakteriologie und der Fehlerquellen in sechzehn Vollesungen. Von Professor Dr. WILHELM LIEPMANN, Privatdozent für Gebürtshilfe und Gynäkologie an der Friedrich Wilhelms-Universitat zu Berlin. Dritte, neudurchgesehene Auflage. Berlin: August Hirschwald, 1920.

THE first and second editions of this atlas appeared in 1911-12 and the appearance of the third was necessarily delayed by the war. The excessive costs of bookmaking made it necessary to omit many new illustrations. Nevertheless, the number of the latter reaches 409, the majority in more than one color. The large vascular trunks are commonly represented in red and blue, muscular tissue in pink, bone and connective tissue in yellow, etc. The number of pages of text is increased from 456 to 488. The author apologizes because the highly calendered paper of the earlier editions is replaced by the dull finish product of the postbellum period.

UEBER DIE ENTWICKLUNG UND DEN AUSBAU DER SUPRASYMPHYSÄREN SCHNITTENTBINDUNG AN DER UNIVERSITÄTS-FRAUENKLINIK, TUBINGEN. Von Dr. EMIL VOGT, Oberartz der Klinik. Berlin: S. Karger, 1921.

THIS brochure covers both the classical and the abdominal cervical or extraperitoneal cesarean sections. The following comparison is found at the close of the book: the author has collated 778 cases of extraperitoneal section from 10 clinics in which material 17 mothers and 11 children were lost. This is compared with the same number of intraperitoneal sections from a great variety of sources in which the figures were very slightly lower, although practically identical. But in the future it is apparent that the intraperitoneal cervical section will displace the extraperitoneal method, and will also wholly dispense with the classical cesarean section.

DIE THERAPIE DER PLACENTA PRAEVIA. Von Professor Dr. F. HITSCHMANN. Berlin: S. Karger, 1921.

THIS brochure of 174 pages comprises sections on the mortality of child-bed fever, the doctrines of Krönig and Sellheim concerning placenta previa, and the author's personal research into the course of the afterbirth period, the causes of hemorrhage in placenta previa, and combined version, metreurysis and cesarean section in the management of the condition. He has assembled nearly 6000 cases of placenta previa in the aim of determining the cause of fatal hemorrhage. Of this number 236 bled to death—about 4 per cent. In one-half of these the blood came chiefly from the placenta, but in 34 per cent. its source was rupture of the cervix (or uterus), while in small fractions hemorrhage was due to atony of the uterus or adherent placenta. The management must therefore depend on the correct diagnosis of the source of the hemorrhage.

THE WASSERMANN TEST. By CHARLES F. CRAIG, M.D., M.A., F.A.C.S., Lieutenant Colonel, Medical Corps, United States Army; Professor of Bacteriology, of Parasitology and Preventive Medicine, and Director of Laboratories, Army Medical School, Washington, D. C. Formerly Curator, Army Medical Museum, and Commanding Officer, Yale Army Laboratory School. Second edition, revised and enlarged. Illustrated with colored plates, and sixty-one tables. Price, $4.25. St. Louis: C. V. Mosby Company, 1921.

IN the main this volume deals with the Wassermann test, the essential feature of which consists in the use of the antihuman amboceptor system presumably made necessary in Army laboratory work at such posts where the supply of antisheep amboceptor would be unobtainable.

Although the volume deals largely with a discussion of the Craig system for conducting the complement fixation test in syphilis, other standard methods are included, such as the Hygienic Laboratory modification (antisheep amboceptor), Noguchi's modification, Kolmer's modification and others. A few pages are devoted to the study of the effect of low temperatures in incubating the complement antigen and patient's blood serum, a procedure that receives much attention in the hands of modern investigators.

In addition to an authoritative discussion of the Wassermann test the serology of the cerebrospinal fluid and its characteristic changes in disease are also discussed. A carefully selected bibliography is included.

LES CARDIO-RÉNAUX. Etude Théorique et Pratique par le Docteur O. JOSUÉ et le Docteur MAURICE PARTURIER. Monographies de Cardiologie Clinique publiée sous la direction du Dr. O. JOSUÉ. Paris: E. Le François, 1921.

THE first chapter of this small volume is devoted to the socalled spurious cardiorenal subject who suffers primarily from asystolia, the renal lesions being those of stasis only. These subjects like the true cardiorenal present oliguria, hydremia, azotemia, albuminuria, edema, etc. This condition may also end in uremia. The true cardiorenal subject has primary renal retention with secondary cardiac involvement. There are several syndromes in which the cardiac or renal symptoms may predominate. Chapter III is devoted to physical diagnosis and tests of renal permeability, etc., while Chapter IV deals with the general principles and detailed application of treatment.

MOTHER AND CHILD. By EDWARD P. DAVIS, A.M., M.D. Professor of Obstetrics in the Jefferson Medical College, etc. Fourth Edition, Revised. Philadelphia: J. B. Lippincott Company, 1921.

THE first edition of this work appeared in 1902 and the third in 1911. Nearly a decade, therefore, has elapsed between the present and last editions. The author states that the book has been brought up to date and numerous additions made to the text, including facts of recent interest concerning the care of the mother and the latest advances in infant feeding. The book, however, is really an abridgment of the much more pretentious volume published originally by the author and Keating in 1902, which contained 472 pages as compared with the 278 pages of the present volume.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Fifty-fifth Annual Meeting.
Held at Atlantic City, June 14-16, 1921.

DR. PHILANDER A. HARRIS OF PATERSON, PRESIDENT, IN THE CHAIR.

First Day—Tuesday, June 14.

The Late Results of Gastroenterostomy for Chronic Ulcers and Acute Perforating Ulcers.—DR. EUGENE H. POOL of New York City read an oration in surgery with this title. The paper was an attempt to investigate the merits and demerits of this procedure in a total of 75 cases, 8 per cent. of which were in the vicinity of the pylorus. The proportion of gastric to duodenal ulcers could not be accurately stated. Posterior gastroenterostomy was performed in all but one of the cases. In 30 cases, something more than gastroenterostomy was done. Five of patients died. An effort was made to estimate the late functional results in the other 70 patients, but only 54 cases were traceable. These were followed for periods varying from six months to six years. In 40 of the 54 cases followed, the ulcer had been parapyloric. Of these cases, 82 per cent. were apparently successful, and 18 per cent. were failures. Forty, or 70 per cent., of the 54 patients whose cases were followed were well at the last report, and complained of no untoward symptoms. In 11 cases, the results were poor. The speaker placed stress on the necessity for keeping the cases under supervision after the operation. In regard to acute perforations, he stated that little mortality followed operation within six hours; but that after that period, the mortality would increase. Operation as late as twenty hours after an acute perforation gave a mortality of 60 per cent. He thought that perforations could be avoided to a considerable extent by timely treatment of chronic ulcers. In closing perforations, the sutures should be placed so as to avoid obstruction of the pylorus. He stated that two out of three patients would do well after closure of the perforation only; but that a definitely indicated late gastroenterostomy in these cases was better than an unnecessary prophylactic gastroenterostomy in the beginning. With more care in the operative procedure and proper regulation of these cases, he thought that better results would be obtained. Although the series was small and the cases had been followed for indefinite periods, the author considered that some significance might be attached to the analysis of these results. While it was unknown at what period after operation freedom from symptoms might be taken to indicate permanent relief, he said that in no case did a recurrence of the symptoms begin later than fifteen months after the operation.

A Survey of Modern Medicine; Newer Methods in Diagnosis and Therapy.—DR. MARTIN J. SYNNOTT of Montclair read this paper as the Oration in Medicine. In answer to the question sometimes asked, whether, with all the new agencies, human life had been greatly lengthened, he stated that in his opinion it had been. He based this opinion upon the statistics of a reliable life insurance company. In a group of sixteen million insured wage earners, the death-rate in 1920 was nine per cent. less than in 1919, and 25 per cent. less than in 1911. There had been a reduction of two-fifths in the death-rate from tuberculosis in nine years, which meant a considerable addition to the life span of the working population of the United States and Canada. According to vital statistics, the average lifetime in the United States in 1896 was 22.7 years, and had risen gradually to 38 years in 1910. When the economic and living conditions among the poor and the industrial groups of the population became sufficiently improved, the speaker thought that much greater progress would be possible. This had been demonstrated at Framingham, Mass., where the campaign of education and nursing conducted by the Community Health Center had produced a marked decline in disease incidence. With greater knowledge in preventing and controlling various epidemics, infections and accidents, and with a greater knowledge of the cause and treatment of metabolic disorders, he believed that they might look forward to a new era of health and efficiency. Preventive medicine, he said, must begin in childhood. Physicians must learn the principles of proper infant feeding and the application of child hygiene. Preventive medicine and surgery had already accomplished much, but would, he thought, accomplish much more in the near future. There must be effective coordination between the internists and the specialists. The dentist and the oral surgeon must keep abreast of modern progress, and there should be a close understanding between them and the medical man.

Carcinoma of the Rectum.—DR. GEORGE J. SOMMER of Trenton, in presenting this subject, confined himself to the symptomatology and diagnosis of the cases in their early stages. He considered cancer of the rectum and pelvic colon curable by surgical means, if recognized early, and said that lack of diagnosis depended on insufficient investigation and examination, and upon poor interpretation of the history. The use of the rectal touch and the proctoscope, supplemented by the *x*-ray and the search for occult blood in the stools, would, he believed, greatly help one to make an early diagnosis, and thus reduce the lamentable results now obtained in this class of cases.

DR. HENRY B. COSTILL of Trenton thought that a campaign of education would be necessary before these cases could be seen early enough for operation to be of any value. Even the particularly good mortality that Dr. Sommer had reported, the speaker considered rather discouraging. He called attention to some of the early symptoms that were often overlooked, the physician believing them due to hemorrhoids, such as a little indefinite pain along the sacrum, a little mucus in the stools at times, possibly a little blood stain, and sometimes a little free blood. He felt no doubt, after many years of observation, that a tendency to cancer was very often hereditary.

DR. GORDON K. DICKINSON of Jersey City called attention to another symptom, gastralgia at the time of evacuation or just before, disappearing shortly afterward, and said that this symptom might be present for months before the patient showed any other. He thought that it was best to call cases of piles rectal carcinoma until they were proved not to be such. After colostomy, dieting and other preliminary care, he considered no surgical procedure more satisfactory than to push a tube into the anus, suture it there and wait.

The Nursing Problem in New Jersey.—DR. GORDON K. DICKINSON of Jersey City presented a short paper on this subject, in which he stated that he had suggested that the Association of Nurses approach the hospital in the same way as was done by the American Medical Association. The nurses being sisters in medicine, he thought that the medical profession should join with them for their mutual benefit. He said that the medical profession had been derelict more than once in failing to note what the public needed and to give it to them. Thus arose the various "pathies." He thought it would be well to suggest to the nurses that there was a public need of nurses for the sick of the middle class, that the trend toward salaried positions was too great, and that the idealism of the early martyrs of the nursing profession was not the ideal of every nurse at present. If this condition were to continue, and some way were not found to increase the number of women entering the training schools, he was of the opinion that the nursing profession would be extinct in another generation or sooner, or that the legislature might rudely intervene.

DR. ALEXANDER MCALLISTER of Camden stated that only the daughters of well-to-do people got a college education and they were not keen on going out to do nursing. He did not think that the medical profession could afford to let things go on until it was made impossible altogether for ordinary healthy, sensible, ambitious girl to train because her family had not had the means to provide her with a high school or college education.

DR. JOHN C. MCCOY of Paterson had changed his

viewpoint in recent years concerning the matter. He had believed in the higher education of nurses, but he now thought that there was a great demand for women such as they had previously obtained from the training school. He believed that the time was quite near at hand when two classes of women would be trained for nursing, one capable of filling the various positions offered them in the outside world, and the other to do the work of daily nursing. He said that he differed with Dr. Dickinson on one point, because he had found in his own part of the state that not even those who could well afford to pay for it could get proper nursing service in many cases.

Dr. DICKINSON of Jersey City said that he had meant to explain that the nurses immediately get on the defensive if you direct them; and he felt that it was more politic for the present and immediate future to put the whole responsibility on them. He thought that they should tell the nurses to get busy and solve this problem, and that if they did not do so right away, the doctors would solve it for them.

A Review of the History of Medicine.—Dr. PHILANDER A. HARRIS of Paterson presented this paper as the President's Address, in which he considered the various cults in chronological order, from the most ancient times to the preseit day, beginning with Hippocrites and ending with the osteopath and the chiropractor. He then considered specialism as it exists in the regular medical profession, there being thirty or more specialties. He thought that there should be but one school of medicine, whose members should be at liberty to use any agency, however obtained, and, if they so desired, in the matter employed by any of the healing cults.

The Electrocardiograph and Its Clinical Applications.—Dr. HARVEY M. EWING of Newark said that the electrocardiograph would diagnose the irregularities of rhythm, some of which could not be diagnosed otherwise; various types and degrees of heart block; and myocardial disease, in a constantly increasing number of cases. He considered the instrument of great value in checking therapy, especially when digitalis was being used. He stated that the instrument would not show valvular disease nor the functional capacity of the heart; but that it would show tachycardias, the preponderance of one or the other ventricle, and irregularities of systole. He stated that the instrument consisted in a very delicate string galvanometer and a recording apparatus. The galvanometer was composed of an electromagnate between the poles of which was suspended a very fine fiber of conducting material. Through this string passes the electric current from the heart; and, according to the old law of physics relating to the conductor in a magnetic field, a string will be deviated in one or the other direction, the extent and character of the deviation depending practically upon the extent of the current from the heart, its direction of flow and its duration. The movements of the string are projected by a light through a series of lenses upon a moving sensitized film, which photographs the resulting curve.

Dr. LOUIS R. BLANK of Newark stated that McKenzie had demonstrated a simultaneous contraction of the ventricle and auricle to be one of the most important signs of impending death. This was solely a muscular contraction, and had nothing to do with the bundle of His. Another thing to which the speaker called attention was a lymphatic pulse, showing a weakness and dilatation of the auricle.

Experience in Reconstructive Bone and Joint Surgery.—Dr. ROBERT E. SOULE of Newark, in this paper, took up osteomyelitis; Pott's disease; osteoarthritis of the spine, hip and knee; bone grafting in fractures; treatment of flat-foot; permanent correction of club-foot; and operative correction of deformities of the long bones. He said that in osteomyelitis, one should not think only of the immediate result, but also of what the ultimate outcome was to be. The treatment of the shaft should go hand in hand with that of the acute infection. He stated that regeneration was not to be expected in pure tuberculosis. For this to occur, there must be a mixed infection.

Dr. BASSIN of Poughkeepsie, N. Y., said he had found that the pin graft was very excellent, but that the joints were very painful unless there was complete arthrodesis. An arthrodesis could be done in children, but not in adults. In cases of paraplegia, Dr. Bassin always did a lengthening of the tendons. In flat-foot, he had been taught that there was always a luxation of the astragalus; and that therefore the deformity could be corrected without an open operation. He was inclined to believe that too much reliance could not be placed upon a bone transplant or bone peg. Unless the patient was in very good health, there would be a tendency to subsequent infection and osteomyelitis.

Dr. H. D. CORBUSIER of Plainfield said that a great many cases of bone graft considered successes really were not. He thought that the reason was that they had not waited long enough after the healing had taken place before putting in the graft. He thought that a bone graft should not be attempted in less than six months unless the wound had healed by primary union. By means of physiotherapy, the speaker stated, a person could be gotten to work much sooner. Dr. Corbusier had seen cases of spasticity in which early tenotomy would have been very beneficial. In regard to putting a bone pin in the astragalostaphoid joint, he had thought that it was not the thing to do so in many of these cases. In a young person, he did not think it was necessary, although it gave a little better arch.

Dr. SOULE said that he had had a case in which there was pain for three years after the operation, but that the vast majority of the patients had gotten along very well. He said that there were some devices that could be used to guide the foot and keep it from a pronated position.

Dr. F. W. PINNEO of Newark said that it was clear that one could expect the bone to grow in its new site and to have static and dynamic recovery. He thought that if they could awake in the soldiers an interest in their reconstruction occupation it would be a valuable therapeutic aid.

Dr. G. H. SEXSMITH of Bayonne mentioned the treatment of hip joint disease in the Lorenz clinic, and said that the plaster casts were applied with an immense amount of cotton giving the child a chance to wear the case for two years without its causing pressure. He asked Dr. Soule to state what he thought about the relative merits of the use of the plaster cast and that of the brace, with a raised shoe on the other side. Dr. Sexsmith said that he would say that the bone graft should not be put in for six months after healing in ordinary infection, and not until a year afterward in tuberculous infection.

Dr. SUTPHEN of Newark thought that Dr. Soule had neglected to mention the fact that one frequently found a fair number of people who did not have the so-called osteogenetic power to carry out the supposed result of the bone graft.

Dr. SOULE said that one did sometimes run across cases that seemed to have a lack of activity in bone generation. He recalled only two cases in which he did not get final union. One was in the spine and he attributed the bad result to employing old kangaroo tendon. In the other case he attributed it to allowing weight bearing too soon. Dr. Soule considered fixation the preferable method if it could be maintained for a long enough time to control the situation. The relaxed foot, he said, was the condition which this pin arthrodesis really applied. It would lead on to more deformity if not so treated.

Second Day—Wednesday, June 15.

Address of the Third Vice-President.—Dr. WELLS P. EAGLETON of Newark thought that doctors should realize that in certain diseases, personal manipulation of the patient is a valuable therapeutic measure. He believed that this not only gave the patient the impression that they were actually doing something for him, but that the personal attention and manipulation actually did do something for him, scientifically and psychologically. He thought that medical men were too careless about trivial matters. They should be more definite in their directions to their patients. For instance, if they told the patient to take exercise, he might simply take a walk the next day and then stop. He thought they had often gone astray in their diag-

nosis because of this lack of attention to details. Because a patient has scarlet fever, a self-limited disease, they should not neglect trying to relieve the sore throat and the headache. The medical profession should realize that they must become an important part of the body politic. If the physician was not a public citizen, the average mediocre man would have lost the uplifting influence of the more intelligent part of the community. It was their duty to instruct the politicians in all matters pertaining to public health. It was their duty to supply the nation with the expert knowledge that it should have on health matters. There should be a Secretary of Public Health in the Cabinet of the President of the United States. In Congress and in every Legislature, a certain proportion of the members should be physicians. If the Republic was to continue, every educated man would have to make himself a factor in the political arena.

Surgical Treatment of Burns with Special Reference to the Acetic Acid Treatment.—Drs. GEORGE M. DORRANCE and LOWRAIN E. MCCRAE of Philadelphia presented this paper, which was read by Dr. Dorrance. He said that in the acetic acid treatment, they were attempting to overcome the pathological changes that occurred in burns. They considered the results obtained by this method of treatment superior to those from others for the reason that it more nearly fulfilled the requirements. Under the ordinary treatment of burns, he stated, one would notice that on the third or fourth day there was a gradual rise in temperature and an increase in pulse-rate. At the same time, the slough would become generalized and encrusted throughout the injured area. Underneath the crust, a chemical change was taking place, due to the formation of toxalbumins, the absorption of which was productive of a rise in temperature and toxic symptoms. To overcome this, they used one-half of one per cent. acetic acid in water. They had found that the acetic acid absorbed the crusts and the underlying material from around the edges, but was unable to penetrate the crust. To prevent the absorption of the toxalbumins and to allow the acetic acid to penetrate, they made multiple crisscross incisions with a knife or wet-cup blade, and immediately applied continuous wet dressings of one-half of one per cent. acetic acid. Each day thereafter, it was possible to remove small amounts of slough with forceps and scissors; or they would float away of themselves in the daily bath of bicarbonate of soda that was given the patient. By this method, the length of treatment of the burn was perceptibly lessened. They had not encountered the complication of tetanus since using this method, but they did not consider this any reason for not giving tetanus antitoxin.

Dr. E. S. CORSON of Bridgeton suggested the use of the positive pole of the galvanic current in the treatment of keloid. A four per cent. solution of theocinamin with salt solution in glycerin had had a good effect on bad contractures on the back of the hand.

Dr. H. I. GOLDSTEIN of Camden remarked that the most important consideration in severe burns was to save the life of the patient. The fact that many of these patients died of severe acidosis, he considered of the greatest importance. He asked whether Dr. Dorrance had found acidosis diminished by this method of treatment. He thought that if they could find out what caused the formation of keloid in the negro, in preference to the white person, it might lead to their finding some better method of prevention.

Dr FRANK DEVLIN of Newark did not agree with Dr. Dorrance regarding the percentage of takes in skin-grafts. He thought that a great deal depended on the tone of the skin and the treatment prior to the application of the skin, as well as on the method employed.

Dr. W. J. CHANDLER of South Orange said that the negro was more subject, also, to fibroid tumor than the white person. He wondered whether there might not be some histological connection between keloid and fibroid tumor.

Dr. BASSIN of Poughkeepsie said that in treating burns about the neck or abdomen in children, he thought the Bradford frame or some other old-fashioned frame was better than the Balkan frame. Burns about the neck should be treated like a wry neck.

Dr. CHANDLER said that skin tumors, or cancers, were extremely rare in the negro race.

Dr. DORRANCE said that he had used four per cent theocinamin, but he did not apply it with the electrical method. He injected it under the skin, and then massaged it in. The results from its use were not very good. He had found acidosis common, but had not had much trouble from this source since using the Murphy drip. He gave the patients large amounts of water internally, and a daily bath in bicarbonate of soda solution.

Hay Fever and Its Treatment with Glycerinated Pollen Antigen.—Dr. R. A. CLOCK of Pearl River, N. Y., stated that tests had shown that the majority of persons who were sensitive to one pollen were also sensitive to other pollens of the same biological group; so that an extract of one pollen or any combination of pollens of one group could usually be employed to test or treat persons who were sensitive to pollens belonging to that same group. To produce uniform results, the pollen extract used must be constantly of uniform potency. Pollen proteins, when extracted in physiological salt solution or in dilute alcohol, would become denatured and lose most of their specific antigen properties in three or four weeks. Such extracts, therefore, were uncertain in their action as desensitizing agents, unless used when freshly prepared. Pollen antigen prepared by extracting the dried pollen in 66⅔ per cent. glycerole and 33⅓ per cent. citrated sodium-chloride solution, formed a stable preparation, not losing its antigen properties after having been stored in the ice-box for twenty-two months. A chemical analysis for antigen content, he did not consider a reliable method for determining the antigen power of pollen extracts, because it did not differentiate between the antigenicity of active protein and that which was inert or denatured. Glycerolated pollen antigen was standardized in pollen serum of the complement fixation method, which accurately determined the amount antigenically active pollen protein, and thus insured accurate dosage. Dr. Clock further stated that not only did the glycerolated pollen antigen possess the antigenic principles of freshly prepared aqueous or alcoholic extracts of pollen, but it also exceeded such preparations in that respect. The antigen substances of pollen were more completely extracted by the glycerolated chloride method than by any other yet described. The dosage consisted of fifteen doses of a gradually increasing number of pollen units. When treatment with this accurate dosage was started six weeks before the hay fever season, the patient was usually rendered refractory to large amounts of pollen during the pollinating season. According to an analysis of 1972 clinical reports from physicians in all sections of the United States who had used the glycerolated pollen antigen method during five consecutive years, it showed a protection or relief from symptoms in 84 per cent. of the cases, with a remarkable uniformity of favorable results each year in every locality. These favorable results were indicated by complete absence of hay fever; mild hay fever symptoms lasting only a few days, in those patients not completely protected; the fact that the attack was shortened by treatment during the hay-fever season, and the symptoms made milder; asthmatic symptoms being prevented or rendered milder and less troublesome; and the possibility of patients remaining in their homes and at their usual work during the hay-fever season for the first time in years. In view of these favorable results, the author thought it fair to state that the method of giving prophylactic injections of the glycerolated pollen antigen early in the season offered the best means of any method thus far advanced for the preventive treatment of hay fever. It would no longer be necessary to forsake business during the summer months and retire outside the zone of the offending pollinating plants, which was formerly the only rational therapeutic measure, and one that was expensive and time-consuming. With the glycerolated pollen antigen treatment, however, the majority of hay-fever sufferers were very successfully desensitized, and could continue to transact their business in their accustomed surroundings. He said that the value of this treatment had been definitely established.

Dr. W. B. JOHNSON of Paterson asked where the antigen referred to could be secured. He thought it desirable to know this, because, by using four different kinds of antigen, the whole field could be covered.

Dr. CHARLES J. CRAYTHORN of Trenton said that his daughter was suffering from hay fever, and that he had tried everything that he had ever heard of in the hope of benefiting her, but that every method of treatment had proved a complete failure. He also had a physician friend whose wife had the same trouble, and none of these serums or antitoxins had done her any good. One firm had prepared a special one for his daughter, but that also was a failure. He said he would be glad to try Dr. Clock's method.

Dr. H. I. GOLDSTEIN of Camden spoke of an instance in which so-called hay fever had been produced by the very free use of face powder made from rice. The perspiration in the summer induced her to use it more freely at that time, with the result that it caused a hypersensitiveness to it. In order to discuss such a broad subject intelligently, he thought one would have to consider asthma and various anaphylactic states, which time would not permit.

Dr. E. S. CORSON of Bridgeton stated that the various preparations of extracts of pollen by the leading houses in the United States had given him satisfactory results. He had had a number of patients who had been subject to hay-fever attacks annually for a number of years, and who had been relieved by these preparations.

Dr. YATES of Paterson stated that he had been a victim of the disease for thirty years. The attacks had varied in length and intensity, but had never been absent altogether. His mother had had the same trouble. He had tried a great many methods of treatment and a great many resorts. His attacks had been worse in the last few years, following influenza. He had had to spend the whole of the preceding summer in the White Mountains, and he told of the conversations on the subject of hay fever that he had had with different sufferers from it that he had met at Bethlehem; many of them were doctors from all parts of the country. He had attended a convention of a society for the study of hay fever, founded by Benjamin Franklin. This society, after all its study, had never been able to determine the cause of the condition. His conclusion, after talking with hundreds of people, listening to many discussions, and reading practically everything written on the subject, was that there were a certain number of persons that would not respond to treatment, no matter what was done.

Dr. CLOCK said that it was not necessary to use four antigens. Four were made, in which different products were used, depending on the section of the country. Ninety per cent. of the people in the East could be treated with one of two extracts: extract of timothy, if sensitive to grass pollen, for the socalled spring hay fever; or extract of ragweed pollen, if of the fall type.

The Importance of Careful Diastolic Blood Pressure Observations in Cardiac and Cardiorenal Disease.—Dr. CLARENCE L. ANDREWS of Atlantic City said that in reviewing most of the records of the past one would be struck by the great discrepancy between the various readings that had been found. He thought that this was due to one of three things: a difference in clinical material used, a difference in the apparatus employed to get the data, or a difference in the interpretation of the results found. On account of this great discrepancy between the blood-pressure readings in different clinics, he had made a study of these cases to see whether he could find wherein the cause of the difference lay. As the result of this study, he had concluded that the early discrepancies in blood-pressure readings had been due to the method used, that of taking only the systolic pressure. He said that the cause of hypertension was not definitely known, but that the evidence seemed to point toward the diastolic pressure as being of diagnostic value, suggesting in what degree the body was eliminating. When found to vary from the normal in a case, he believed that it demanded of the doctor an explanation, even though the systolic pressure was apparently normal. Hypertension cases found in women about the time of the menopause usually tended to right themselves, and need not give one very grave concern. There was an apparent relation between the diastolic pressure and retention of toxic products in the body. In one of his cases this condition did not respond to ordinary methods of elimination, but responded quickly to alkaline treatment. In another case the blood pressure could not be lowered by ordinary means. Such a condition, he thought, should give a grave prognosis, in spite of the absence of symptoms. Another patient had a normal systolic pressure for the age of the patient, but with a diastolic pressure that was checked up by the blood-chemistry findings and showed beginning protein retention. This case cleared up by the use of methods of elimination. This picture should suggest an abnormal condition and a demand for the doctor to look into the cause further. A fifth patient showed how a case, under cardiac strain, might be prognosticated by watching the relationship of the diastolic and the systolic pressure; and also how easily one could be misled, if he took the systolic pressure alone.

Dr. PHILIP MARVEL of Atlantic City thought that there had been more importance placed on the mere reading of the units of hyper- and hypotension than the subject deserved. Hypertension, like fever, he said, was a manifestation of a disease. One should go back of the manifestation and try to find means to conquer the disease. Dr. MARVEL divided socalled hypertension into three divisions: that due to atheroma, that due to endarteritis, and that due to arteriosclerosis. The former two groups could be dismissed, because treatment could have little effect on the changes due to them. In dealing with the last, arteriosclerosis, one should bear in mind that it was a complex condition, involving not only the artery and the myocardium, but also physical changes in the glandular activities of the body. If the arteriosclerosis was engrafted upon an infectious disease, caused by a streptococcus, the physician must have in his mind the arterial and glandular changes incident to that disease. He said that in a normal individual the stimulation of the muscular activity required in raising the position from the horizontal to the perpendicular was manifest in the heart stimulation and activity, the systolic pressure rising, and the diastolic slowly declining; whereas the reverse took place in a pathological condition of the heart. This should teach us that the blood pressure is only the measurement of the resistance in the cardiovascular cycle, plus the amount of force that the ventricle throws into the blood-stream.

Dr. LOUIS N. BLANK of Newark referred to the oscillating systolic blood pressure, which he distinguished from the fluctuating pressure met with in every individual, irrespective of pathological changes. He meant that there were various waves that could be felt when the patient remained in the same position. This oscillating systolic pressure usually produced a high pulse pressure. He then referred to the high blood pressure often found in the menopause, and said that very often the physician, on that account, thought that the patient was going to have an attack of apoplexy. If there was no pathological condition in any of the organs, skatol, in the gastrointestinal tract, might be responsible for the high blood pressure. This was merely a functional disturbance.

Dr. H. I. GOLDSTEIN of Camden stated that affections of the circulatory and renal system were definitely on the increase. In order to recognize and value the pathological indications of blood-pressure variations, he said that it was necessary to know thoroughly the causes for changes in blood pressure during health. It was important to make repeated blood-pressure examinations under most favorable and varied conditions before reaching a decision. Diastolic and systolic blood pressures were affected unequally by posture, exertion, etc. The diastolic pressure tended to vary less than the systolic under most of the conditions that increased tension. The arrhythmias made blood-pressure readings, especially the diastolic, difficult.

Dr. JOHN M. GRAY of Newark thought that the prognosis depended very largely upon whether or not the hypertension was associated with kidney lesions.

Dr. ANDREWS said that although men often said that it was useless to take the blood pressure, because it presented so many variations, he personally thought

that it was as useful as any information that one could obtain. A great variation in the pressure at different readings indicated myocarditis. In regard to skatol, he said that there was a relationship between the amino-acid group and the blood nitrogen urea; and he believed that there was a relationship between these and the diastolic pressure. He thought that it did not matter how the systolic went up and down, if the diastolic could be gotten to stay still. He agreed with Dr. Gray about the effect of renal lesions.

Clinical Pathology of the Thyroid Gland.—Dr. JOHN P. REILLY of Elizabeth, in this paper, stated that chemistry played the principal rôle in determining the active principle of the toxic secretion, with its various manifestations, as exhibited in the subjects, giving a better understanding of the goiter syndrome, and pointing out the safe and danger scale in its course of treatment. This newer knowledge he considered valuable, especially in the class of cases heretofore too puzzling to permit of diagnosis; namely, the thyrotoxicosis of the adenoma type. He thought that the clinical pathology of the thyroid gland was now in a fairly acceptable form.

Dr. JOHN F. HAGERTY of Newark thought that goiter was a much more common ailment than was generally understood. He did not consider the diagnosis of thyroid poisoning easy, and said that many patients who complained of tiring easily, indisposition to work, lack of energy, lack of interest, and palpitation of the heart on slight exertion, were often suffering from hyperthyroidism. This was not recognized, because there was no appreciable tumor in the neck. Large colloid tumors were usually not toxic. In the severely toxic cases the gland did not enlarge because the poison was absorbed as rapidly as it was produced. Unless the condition was diagnosed early, he said, it would have advanced so far that it could not be helped. No better treatment for toxic goiter was known than the surgical. Rest in bed was the best alleviating measure. These patients the speaker considered to be in a state of unstable equilibrium, and he said that the slightest shock would topple them over and cause death. They should be treated with the greatest care. They wasted rapidly, because of the increased metabolism; so they should receive large quantities of carbohydrates. They should not be operated on, unless they could be brought into proper condition to stand the procedure. The basic metabolism records had, he thought, come nearer to furnishing precise data as to when to operate and how far the operation should go than anything else.

Dr. J. W. GRAY of Newark said that the basic metabolism test was so complicated that it was not possible for the majority of workers to make it. He mentioned that preliminary reports had been given on a new complement-fixation test for picking up the protein products in the blood. This test was simple, and would prove to be as valuable as the basic metabolism test.

Dr. H. I. GOLDSTEIN of Camden emphasized weakness as a lead toward the diagnosis of a hyperthyroid condition; and also loss of weight and toxemia. After ruling out tuberculosis, these should lead toward the diagnosis of hyperthyroidism, even without goiter. He considered Sippy's test valuable, and said that a marked blanching of the conjunctiva following it meant a disturbance of the endocrines of the thyroid. In many of these obscure cases, none of the tests could be depended upon.

The Election of Officers resulted as follows: *President*, Henry B. Costill, Trenton; *First Vice-President*, James Hunter, Jr., Westville; *Second Vice-President*, Wells P. Eagleton, Newark; *Third Vice-President*, Alexander McAllister, Camden; *Recording Secretary*, William J. Chandler, South Orange; *Corresponding Secretary*, Harry A. Stout, Wenonah; *Treasurer*, Archibald Mercer, Newark.

Neurodermotropic Syphilis.—Barthelemy and Bruant report a remarkable case in which the two types of syphilis were remarkably combined in one subject. After developing tabes with blindness he showed many years later gummata of the palate with extensive ulceration and still later cerebral apoplexy. The duration of the disease had now been 30 years with Wassermann still positive.—*La Presse Médicale.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TUBERCULOSIS AND HOW TO COMBAT IT. By FRANCIS M. POTTENGER, M.D. 273 pages. Price, $2.00. Published by C. V. Mosby Company, St. Louis.

PEKING UNION MEDICAL COLLEGE ANNUAL ANNOUNCEMENT 1921-1922. 86 pages with illustrations.

THE STATE HOSPITAL QUARTERLY. Volume vi, May, 1921. No. 3. 440 pages. Price, 50 cts. Published by the New York State Hospital Commission, Albany.

PHYSICAL DIAGNOSIS. By W. D. ROSE, M.D. 736 pages with 309 illustrations. Price, $8.50. Published by C. V. Mosby Company, St. Louis.

TEXT-BOOK OF TRACHEO-BRONCHOSCOPY. By Dr. M. MANN. 297 pages with illustrations. Price, $9.00. Published by William Wood & Company, New York.

HYPERTHYROIDISM. Vol. i, No. 1, Harrower's Monographs on the Internal Secretions. Edited by HENRY R. HARROWER, M.D., F.R.S.M. (Lond.). Price, $1.50. Published by The Harrower Laboratory, Glendale, California

PRACTICE OF MEDICINE. By Dr. H. DAYTON. 328 pages. Price, $2.25. Published by Lea & Febiger, Philadelphia.

THE EVOLUTION OF DISEASE. By Prof. J. DANYSZ. 194 pages. Price, $2.50. Published by Lea & Febiger, Philadelphia.

FUNDAMENTALS OF BACTERIOLOGY. By Dr. C. B. MORREY. 320 pages with 171 engravings and 6 plates. Price, $3.25. Published by Lea & Febiger, Philadelphia.

MOUTH HYGIENE. By Dr. ALFRED C. FONES. 334 pages with 218 illustrations and 8 plates. Price, $5.00. Published by Lea & Febiger, Philadelphia.

INFECTIONS OF THE HAND. By Dr. A. B. KANAVEL. 500 pages with 185 engravings. Price, $5.50. Published by Lea & Febiger, Philadelphia.

ROENTGEN INTERPRETATION. By Drs. HOLMES AND RUGGLES. 228 pages with 184 engravings. Price, $3.25. Published by Lea & Febiger, Philadelphia.

NUTRITION AND CLINICAL DIETETICS By. Drs. CARTER, HOWE, and MASON. 703 pages. Price, $7.50. Published by Lea & Febiger, Philadelphia.

DISEASES OF THE SKIN. By Dr. O. S. ORMSBEY. 1166 pages with 445 engravings and 4 plates. Price, $10.00. Published by Lea & Febiger, Philadelphia.

AIDS TO ELECTRO-THERAPEUTICS. By J. M. REDDING. 196 pages with illustrations. Price, $1.75. Published by William Wood & Company, New York.

PATHOLOGISCH-ANATOMISCHES PRAKTIKUM. By Prof. RICHARD OESTREICH. 316 pages. Price, 54 marks. Published by Urban & Schwarzenberg, Berlin and Vienna.

TASCHENBUCH DER DIAGNOSTIK UND THERAPIE DER LUNGENTUBERKULOSE. By Prof. H. GERHARTZ. 296 pages with 67 illustrations and 16 plates. Price, 72 marks. Published by Urban & Schwarzenberg, Berlin.

THE ALIEN TREATMENT OF DIABETES. By Dr. L. W. HILL and R. S. ECKMAN. 140 pages. Price, $1.75. Published by W. M. Leonard, Boston.

LEÇON INAUGURALE, L'ESPRIT DE LA MÉDECINE FRANÇAISE. By M. LOUIS RENON. 38 pages. Published by L. Maretheux, Paris.

MILCHDRÜSEN BEI DER BEVÖLKERUNG IN FINNLAND. By KAJAVA, SCHRODERUS, WALLENIUS, and WICHMAN. 108 pages with plates. Price, 20FMK. Published by Aktiengesellschaft Sana, Helsingfors.

THE SURGICAL CLINICS OF NORTH AMERICA. Vol i, No. 2. 587 pages with illustrations. Price, $12.00 per year. Published by W. B. Saunders Company, Philadelphia.

NERVÖSE ANGSTZUSTÄNDE UND IHRE BEHANDLUNG. By Dr. W. STEKEL. 672 pages. Price, 78 marks. Published by Urban & Schwarzenberg, Berlin and Vienna.

DIE PROPHYLAXE UND THERAPIE DER ENTEROPTOSE. By Prof. L. KNAPP. 118 pages. Price, 42 marks. Published by Urban & Schwarzenberg, Berlin and Vienna.

Miscellany.

From Portal to Laveran.—The first president of the *Academie de Médecine de Paris* was Portal, elected in 1820; and on the centennial anniversary Laveran is the incumbent in the chair. Of the several papers of historical nature read at the celebration that of Chauffard is of interest. When the Academy was first organized medical France was under the influence of three eminent men. Pinel, at the close of the eighteenth century, had published his nosology. Broussais, in 1816, had promulgated his peculiar views of pathology, which were grievously antagonized by the results of the coming science of pathological anatomy. Laennec had just come to the front with his physical diagnoses checked up by autopsies. Bouillaud, the disciple of Broussais, strove to keep up the latter's prestige before the Academy, while Louis, the successor of Laennec, endeavored to make good the thesis of the autonomy of abdominal typhus Pathological anatomy developed a body of men known as "organicists," who attributed disease to alterations in individual organs and laid great emphasis on physical exploration. Piorry devised a new nosology with all-Greek terminology. Among his innovations were the words toxemia and septicemia. Up to the era of Villemin the various departments of clinical medicine were well represented. Orfila was the great authority on forensic medicine, psychiatry was fortunate in the possession of Esquirol and his school, Ricord and his disciples played the same rôle in connection with syphilography, etc., etc. The vast work of Pasteur is familiar to all.

Of interest is the old work done in inoculating animals with syphilis and the attempts of Auzias-Turenne, in 1852, to cure syphilis by immunization. Not all the eminent medical men aired their life work before the Academy, two of the most eminent outsiders being Duchenne de Boulogne and Charcot, founders of modern neurology. In 1887 Cornil proposed to boil all drinking water when typhoid was prevalent, but the Academy did not officially advise this practice until several years later. The fecal origin of typhoid fever was first discussed in England in 1877, so that nearly a score of years passed before the gap between theory and practice was bridged. The problem of alcoholism has been before the Academy since 1850, and in 1870 Hardy showed its evil influence in erysipelas and pneumonia, and Verneuil in accidents, while the elder Chauffard made the same announcement for tuberculosis. Finally Magnan stated that alcohol opens the door of insane asylums, and Lancereaux studied absinthism and alcoholic cirrhosis.

In 1859 Piorry laid down the wisdom of certain therapeutic resources, such as the use of superalimentation and earthy salts, respiratory gymnastics and bandaging cavities in tuberculosis. The great work of Fournier on the parasyphilitic affections was threshed out at the Academy.

In regard to the germ theory the author resurrects the work of a country doctor, Jean Hameau, who, in 1843, read before the Academy a paper on what he termed "living virus." This substance is contagious, has an incubation period, and can regenerate itself. Quotations from his paper showed the remarkable anticipations of Pasteur's discoveries, the phraseology being often strikingly like modern expressions. The central figure of the century of Academy activities is clearly Pasteur, who dwarfs all others and who has inspired so much of the subsequent advances.

Davilla Rugosa, a Little Known Brazilian Medicinal Plant.—Batta, of the University of Liège, describes this plant in the *Archives médicales Belges* for January, 1921, lxxiv., 1. Some of its leaves were supplied to him by colleagues of Sao Paulo. In order to identify the species he states that originally it was known as the *Davilla Braziliana* and named for Davilla, the Peruvian botanist, who died in 1805. The plant was first used as a local application, its leaves being boiled to the point of softening as an application to inflamed surfaces. If conveniences for boiling were lacking a poultice was made from the cold, macerated leaves. Today the leaves, a watery extract of the same and sometimes a tincture are employed. The plant appears to exert an analgesic and vasoconstrictive action on inflamed surfaces, as in orchitis, hemorrhoids, varices, etc. It is said to be far superior in this regard to belladonna leaves, hamamelis, etc. It may be used in an ointment with lanoline and is exhibited internally in the form of a solid extract and pills. Applied to the mucosæ or abraded skin the remedy is analgesic. Given internally there is no apparent physiological action, in doses up to two grams daily. As is apparent from the native accounts of the use of this substance, it is purely an empirical resource. The author subjected the leaves to a pharmacological study. He found no evidence of an alkaloidal active principle, but there is a considerable percentage of tannic acid. It contains no hydrocyanic acid and has no reducing properties. The amount of ash in one sample was as high as 20 per cent., while the tannin in two specimens was over 7 per cent. The plant may be likened medicinally to catechu.

The Earliest Cataract Extraction in Finland.—Nordmann discusses this question of priority in the *Finska Läkaresällskapethsandlingar* for January-February, 1921, lxiii., 1-2. Incidentally the periodical press in Finland goes back 150 years and the anniversary was recently celebrated. About two years after this debut of periodical literature there was placed on record an account of a cataract operation performed in the town of Abo. The title of the publication was "Tidningar utgifne af et Sällskap i Abo," date Jan. 23, 1772. The title of the article was the general one of "News From Abo." The subject with the cataract was the Reverend Dr. Samuel Pryss, aged sixty-six. The cataract first appeared four years before in one eye, while three years later the sight of the other eye became involved. The operation was performed Oct. 1, 1771, by Carl Deneke, in the presence of two physicians, Haartman and Bergman, of whom the former held the title of professor. The operation was recognized at the time as the first of the kind to be performed in Finland. Deneke was a regimental surgeon and had received his medical education in Sweden, Germany, France, and England. He was a native of Stralsund. There is no description of the operation itself, but a full account of the postoperative course. The identity of the man who placed the case on record cannot be fixed.

WHAT MEDICINE OWES TO ITALY.*

By JAMES J. WALSH, M.D., Ph.D.,

NEW YORK.

GENTLEMEN: I think that most of you here probably know that I am an ardent Italophile. I am taking whatever part I can in the celebration this year of the six hundredth anniversary of the death of Dante because I think that he was probably the greatest man that ever lived. His being an Italian was the most natural thing in the world because most of the greatest men of modern history were born in Italy. For years I have been trying to write a book with the title "What Civilization Owes to Italy." I am not sure when it will be printed because in the present state of the printing trade every publisher is shy of big books and how ever could a man write a small book on that subject. After having gathered the material for that volume I am quite convinced that when one has collected the debt that civilization owes to Italy there is so little left to owe to any other nation, at least comparatively speaking, that it is scarcely worth while talking about. My only reason for saying that is that I have spent a good deal of time for years trying to make out the bill. No one knows better than I do that I did not get all the items in, but I gathered up so many of them that I have a very definite idea founded on rather exact data as to how much the debt of the rest of the world to Italy actually is. Now I am not going to tell you that story tonight; I am only going to try to tell you a very small part of it, the debt the world owes to Italy for medicine, but let me make a background of a few of the outstanding debit accounts in Italian history.

Of course everyone recognizes that in art Italy's contribution to civilization is so large as to be quite incommensurable. Practically all the greatest painters are Italian. Only twice in the history of modern civilization has the primacy in painting passed from Italy to other countries. During the seventeenth century for a time scarcely longer than a generation, when Velasquez and Murillo were doing their work in Madrid and Rembrandt and Rubens theirs in the Netherlands, Italian painters, though some of them were really great artists, were of second rank. During the political troubles of the nineteenth century French painters, most of whom, however, had studied in Italy, took the lead for a time, though it must be confessed in a period that had very little of great art in it. In sculpture even much more than in painting Italy is a leader. What names have other countries to place beside those of Donatello, the Pisanis, Ghiberti of the Baptistery Doors, the Della Robbias, Leonardo da Vinci, and Michelangelo, not to mention others in the domain of sculpture.

What is true in painting and sculpture is just as well exemplified in architecture and the arts and crafts. Civilization's debt for these is well nigh incalculable. In architecture we owe the Byzantine not to Byzantium but to Italy. The finest example of it is St. Mark's in Venice. Gothic architecture, that is the use of the broken arch in great monumental buildings, is said to have been first tried in Italy. The Crusaders saw it in Sicily and brought it home with them after the Crusades and then developed it wonderfully in their great cathedrals in the northern countries where in the winter time they needed so much light and therefore demanded the high buildings with the large windows. Renaissance architecture which has so deeply influenced the modern time is all Italian. Spanish architecture was largely influenced from Italy. French Renaissance architecture, so-called, drew most of its ideas from Italy. Not a few of the châteaux on the Loire were built by Italian architects, notably Fra Giocondo. Our handsomest building in New York, built in the twentieth century, is the *New York Times* building, which, of course, is nothing but Giotto's tower set down on Broadway in 1904. Look at the beauty of the New York Public Library some time and realize how much of it is due to Italian influence both within and without.

Auction sales in recent years have served to show us a little of what we owe to Italy for beautiful arts and crafts. Mr. Pierpont Morgan paid $60,000 for the Cope of Ascoli, though the jewels had been removed from it, because his experts told him that it was the most beautiful piece of needlework in the world. It was made seven centuries ago in a little convent in north central Italy. Go to Anderson's some time or the American Art Galleries when a sale of Italian Renaissance furniture is on and see what prices these antiques command. In metal work the Italian artists were far ahead, their statuettes and bronzes now command prices that are fairly staggering. I remember being at a sale where a censer, that is a thurifer as used in religious services, was being sold. The auctioneer said that unless $55,000 was offered for it it would not be sold. It was less than eighteen inches high. Just a piece of bronze made by a student of Leonardo da Vinci and not Leonardo himself. I ex-

*An address delivered before the joint meeting of the Italian Physicians Association of America, the Italian Medical Society of New York City, and the Italian Medical Society of Brooklyn, at a dinner given at the Hotel Pennsylvania, on the evening of June 4, 1921.

pected to see that thurifer set back, but no, someone bid $60,000 and then sixty-five and then seventy, I do not know how much higher it went, but something near $80,000. The papers the next day said that it was knocked down for that sum. I should hate to have it knocked down on me for any such sum. What I wondered at was that they called it knocking it down, and yet there is no doubt at all that the buyer considered it worth it. One of Raphael's pictures, the Cowper Madonna, 18 x 24, a little bit larger than a pocket handkerchief, commanded three quarters of a million in a sale some years ago in London. Evidently a little of the debt to Italy is being collected.

What is true in the arts is just as true in literature with perhaps a little less significance. To an Italian, Francis of Assisi, we owe what is known as the "Hymn of the Creatures" which Matthew Arnold proclaimed the great beginning of modern vernacular literature. Francis of Assisi was really one of the earliest of the Trovatori or Troubadours, his love being for the divine rather than for the human. Dante, who came at the end of the thirteenth century, I always think of as, as I have just said, the greatest human being that ever lived. That seems a great deal to say and if I were the only one who said it I should feel dreadfully lonely, but something like 10,000 books have been written about Dante and some 20,000 more or less important articles. The Dante library at Cornell has a catalogue in two large octavo volumes, six hundred pages altogether, of nothing but titles of books and articles about Dante printed in double columns so as not to take up too much room. Ariosto probably influenced the poets of Europe more deeply than any other poet, except the classics, have ever done. Ariosto's "Jerusalem Delivered" was the most read poem in Europe for two centuries. Before the Italians made their own vernacular literature they had made a great literature in Latin. To them we owe the great rhymed Latin hymns. The "Dies Iræ" is perhaps, as Professor Saintsbury of Edinburgh said, the greatest wedding of sense and sound that has ever been made. Only Dante and Shakespeare have ever equalled it, no one has ever excelled it. The Stabat Mater, St. Thomas Aquinas' great hymns, and St. Ambrose's great contributions to hymnology must all be set down to the credit of the Italians. They invented the modern novel and the modern short story and Macchiavelli is the greatest historian of modern times in spite of the fact that his first name, Niccolo, is said to be the origin of our English "Old Nick," for the devil.

What country in Europe can show anything like so large a debt on the part of world literature as this of Italy? In music, however, the debt is even larger. Italy invented the opera, both serious and comic, and her musicians have given us the greatest operas. For a while in the later nineteenth and earlier centuries, Italy's primacy in music seemed disputed, but surely not seriously. Even at the present moment, when all music is in a decline, the Italian composers have written the popular music for the world. Think of what our programmes at the opera would be without Rossini and Verdi and Bellini and their Italian musical compatriots! Think of all that Donizetti has done in lighter vein. All our theater comes from Italy, the horse-shoe shape with its boxes, movable scenery on the stage, the frame which makes the stage scene a picture, and all the rest of the architecture. On the other hand all our ecclesiastical music is Italian. We have the Ambrosian hymns, the Gregorian music, the plain chant that is now being revived, and all of Palestrina's magnificent contributions to church music. Besides we owe the finest violins ever made to the Italians and the construction of the pianoforte in the form in which it is and the development of the harp, to say nothing, alas, of the hand organ, for, unfortunately to them, we owe also the first "canned" music. We trust the musical judgment of the Italians more than that of any other people. The Scala at Milan still continues to be the world's highest court of appeal in musical judgment as regards both voice and musical composition.

It may perhaps be thought that in the arts Italy was so far in the lead of the rest of the world that naturally her accomplishments were very great, and undoubtedly greater than those of other people. Perhaps some might be inclined to think that in the childhood of the race we took to art and Italy was the pioneer of modern times; but now that mankind has grown up we have taken to science and of course in that Italy lags far behind the rest of the world. I suppose that there are some people who would actually be ready to say something like that. We are so little accustomed to associate Italy with science because until comparatively recent years we have known almost nothing about the history of science, we are therefore inclined to conclude that since we knew nothing about it, there must be nothing to know. The history of science, however, sets Italy up in the greatest place in that department too. I know that the names of the great founders in modern science are not Italian, but then who knows the history of their education and environment? Copernicus, the father of modern astronomy, was a Pole, but he wrote his great book on the revolutions of the celestial bodies after he had studied for many years down in Italy; indeed, the first draft of it was made down there, and he dedicated it to the Pope with permission. The greatest disciple of Copernicus, and the man who more than any other helped to bring in the Copernican system, is Galileo, the Italian whose name deserves to come just after that of Copernicus in the history of astronomy. Vesalius, the father of anatomy, and by that same token of the morphological sciences in biology, was not Italian, but a Belgian, but after making his medical studies at Louvain he looked around for graduate work, could not find it in Paris, though he tried, so he went down to Italy and stayed there for twenty-five years and wrote his great textbooks down there. Though he was a foreigner they made him professor of anatomy and encouraged his work in every way. Harvey, the father of modern physiology, through his description of the circulation of the blood, had been a student in Padua and makes his asknowledgments to his Italian masters at the beginning of his work. His English biographer says "there can be little doubt that the seed then sown fell into suitable soil and that to Fabricius (Padua) we owe the awakening of the spirit of inquiry and observation which ended only with Harvey's life but which in its course enriched the world of knowledge and

of thought "with one of its grandest generalizations" (Bowie). Indeed, there is more than a question whether Harvey did not obtain the complete idea of the circulation of the blood while studying in Italy, for the pulmonary circulation had been described by Realdo Columbo and the general circulation by Cesalpino, but that does not lessen Harvey's merit, for he made the demonstration and formulated the teaching which made the world accept the idea.

How many other names besides Fabricius, Columbo, and Cesalpino are famous in the teaching of medicine in Italy anyone who knows the modern development of the history of medicine will readily realize. Malpighi deservedly has his name attached to more structures in the human body than any other and is rightly called the father of histology. Morgagni was greeted by Virchow as the father of modern pathology. The Englishman, Richardson, said of his book, "The Seats and Causes of Disease," to this day no medical scholar can help being delighted and instructed by the study of this wonderful book. To move into it from a body of current medical literature is like passing from the periodical flux of current general literature to the perusal of a Shakespearean drama, the "Pilgrim's Progress" or "Paradise Lost." We shall have something to say of other distinguished contributors to the medicine and surgery of the world and that is quite literally what they were in the second part of this paper when I come to talk more particularly of medicine and surgery.

In education Italy has been the schoolmaster of the world for advanced teaching for seven of the last eight centuries. Whenever anybody from the beginning of the twelfth down to the end of the eighteenth century wanted to get a better education than he could get at home in any country in Europe practically always he went down to Italy to secure it. This was always true for art and sculpture, but also for scholarship of all kinds and above all for science. All the great founders of modern science have studied in Italy, above all in mathematics, in astronomy, in medicine, and in surgery, and her schools have always been famous in philosophy. At the beginning of the nineteenth century, when Napoleon gave a fresh impulse to French genius for a half a century, France was the home of graduate teaching. After 1879 Germany became the home of graduate teaching, and now the question is, where will advance students go; and we are bidding for them here in America. Before the nineteenth century people went to Italy. Gerald, the Welshman, in the twelfth, Joycelyn of Brakelond in the thirteenth, Chaucer in the fourteenth, Grocyn in the fifteenth; all from distant England, ever so much farther away from Italy than the Pacific coast is now, went to Italy to study. Lanfranc, the first great teacher of surgery at the University of Paris, and his namesake, the Archbishop of Canterbury, as well as his successor at Canterbury, Anselm, were all Italians carrying Italian thought and influence to the West. Guy de Chauliac, often called the father of French surgery, studied down in Italy. It would not be difficult to make this list a long catalogue. During the Renaissance time everybody that could went down to Italy from France, Spain, England, Germany, and such names as Reuchlin, Erasmus, Regiomontanus, Cardinal Nicholas of Cusa, are only examples of Italian students. After the Renaissance no one was considered to be educated in Europe unless he has made the Grand Tour and above all spent a considerable time down in Italy. The magnificent editions made by the early Italian printers of the great books of the world are the best demonstration of the profundity and accuracy of their scholarship.

Above all we in the modern time at a distance from Italy and in a period when we are not very much interested in art or at least not productively interested in it, may be inclined to think of Italians as lacking in profundity of intellect and as never having made serious contributions to world philosophy. Only a very little knowledge of the history of philosophic thought is necessary, however, to correct any such false notions. The great Latin fathers of the Church, Augustine, Jerome, Ambrose, Gregory, are typical examples of Italian genius. Anselm of Canterbury has deeply influenced great thinkers now for nearly a thousand years. Aquinas is considered by many, among them the great Cardinal Mercier of Louvain in our day, as the profoundest thinker of modern times. It is curiously interesting to realize that he was a great poet as well as a great philosopher, an almost unprecedented combination, and some of his Latin hymns are among the greatest ever written. Dante thought so much of him that his poems are fairly saturated with Aquinas, so that it has been said if by any chance the writings of Aquinas should be lost the great principles of them at least could be supplied from Dante's "Divine Comedy." In more modern times such men as Jerome Cardan, Telesio, Giordano Bruno, and Campanella are great figures in the history of philosophy. The work of Telesio "marks the fundamental revolution in scientific thought by which we pass over from the ancient to the modern methods." He lived a century before Bacon, who confesses his obligations to Telesio, whom he frankly hails as "the first experimental observer of nature." Campanella and Bruno are better known because they were persecuted, and Bruno and not Spinoza should have been called "the god intoxicated man." More than any other, he is the founder of that Pantheism which tinctures so much philosophic thinking in our time. Campanella has been called "the audacious Titan of the modern age."

It would be surprising indeed if the nation that thus deeply influenced every phase of human thinking and intellectual development should have failed alone in the application of thought to human problems in medicine and surgery. Almost needless to say it did not. If the debt that civilization owes to Italy is so great as to be almost incalculable, the debt that mankind owes to Italy for medicine and surgery is, if possible, almost higher. It began way back in the later Middle Ages with the foundation of the medical school at Salerno around which there came into existence the University of Salerno, the first university of modern times. It would be easy to think that we could dismiss the Italian medicine of that early day with the thought that after all people knew so little about medical science at that time and were so prone to accept all sorts of impossible ideas for no better reason than that they were strange and sensational and were so in-

tent on all sorts of superstitions, medical and religious, that their medical teaching would be of no significance. Only that we have certain textbooks from the University of Salerno nothing could possibly make us believe that these men reached the solution of a great many modern problems in anticipation of us. Anyone who knows the famous *Regimen Sanitatis*, the manual of health issued by the faculty of the medical school of Salerno in the thirteenth century, is aware that down at Salerno they anticipated all the modern notions with regard to the value of air, exercise, regulation of the diet, rest, and water internally and externally, some seven centuries ago. The textbook of the Four Masters in surgery is another startling demonstration of the power of these early Italian workers in medicine and surgery to anticipate what we are likely to think of as ideas reserved for discovery in our time. They describe operations of all kinds, including trephining, and insist on the absolute necessity of cleanliness, especially on days when they were to do a trepanation.

The North Italian surgeons followed up the Four Masters and even went beyond them. They opened up all the cavities of the body, skull and thorax and abdomen, sewed up wounds of the intestine, even did not hesitate to remove portions of it, used metal tubes to keep the severed intestines from leaking, and employed the trachea of animals as absorbable aids to intestinal anastomosis. Such serious operating could not be done without antisepsis and anesthesia, but they had both. Their teaching with regard to antisepsis and the getting of union by first intention is particularly interesting. Professor Clifford Allbutt, Regius Professor of Medicine at the University of Cambridge, corresponding to Professor Osler's place at the University of Oxford, said: "They washed the wounds with wine, scrupulously removing every foreign particle; then they brought the edges together, not allowing wine nor anything else to remain within—dry adhesive surfaces were their desire."

Theodoric comes nearest to us of all these old surgeons. The surgeon who in 1266 wrote: "For it is not necessary, as Roger and Roland have written, as many of their disciples teach, and as all *modern* surgeons profess, that pus should be generated in wounds. No error can be greater than this. Such a practice is indeed to hinder nature, to prolong the disease, and to prevent the conglutination and consolidation of the wound" was more than half a millennium ahead of his time. The italics in the word modern are mine, but might well have been used by some early advocate of antisepsis or even by Lord Lister himself. Just six centuries almost to the year would separate the two declarations, yet they would be just as true at one time as at another. When we learn that Theodoric was proud of the beautiful cicatrices which he obtained without the use of any ointment (*pulcherrimas cicatrices sine unguento aliquo inducebat*), then further, that he impugned the use of poultices and of oils on wounds, while powders were too drying and besides had a tendency to prevent drainage, and the literal meaning to the Latin words *saniem incarcerare* is to "incarcerate sanious material," it is easy to understand that the claim that antiseptic surgery was anticipated six centuries ago is no exaggeration and no farfetched explanation with modern ideas in mind of certain clever modes of dressing hit upon accidentally by medieval surgeons.

It is extremely interesting to read the discussions of these old surgeons with regard to such subjects as cancer and lupus, hydrocephalus, epulis, polyps, ranulæ, and the like. They anticipated our modern laryngology and rhinology which are rightly considered to be very recent developments due more to American enterprise than to anything else, with startling definiteness and details. The description of removing the tonsils reads very much like that in a modern compendium of laryngology. Perhaps the greatest medical and surgical development of these medieval Italian surgeons was the use of mercury in the therapeutics of syphilis. This is probably the greatest therapeutic discovery ever made. It has endured for over six centuries and in spite of the most recent developments is still considered extremely valuable. Many times ever since, as in our own time, arsenic has been lauded as a substitute for mercury, but after a time its use has gone out and mercury has endured. We shall have to wait and see whether mercury or arsenic is to remain as the sheet anchor, for after all salvarsan is still on trial as regards enduring effects. It is interesting to realize what these old Italian surgeons did for the nursing of patients, for they recognized the value of trained care and they erected some very beautiful hospitals. Indeed, some of the Italian hospitals of the fourteenth, fifteenth and sixteenth centuries are among the most beautiful ever built. The Hospital of the Innocents at Florence for foundlings (the Italians used no such crude name for the little patients), and the *Ospedale Maggiore* at Milan, one of whose wings was designed by Brunelleschi, are striking examples of what these Italians did for hospitals.

Anyone who thinks that such good work in surgery stopped at the end of the Middle Ages and that Italy has done little or no good work since does not know the history of medicine as it has developed in recent years. Fallopius, Vigo, Argelata, Savonarola, and others made magnificent contributions to bone surgery. They insisted on the reduction of the dislocation along the same path through which it took place, described fracture of the inner table of the skull with the outer unbroken, and depression without fracture in children as well as many other supposedly modern details. These early Renaissance Italian surgeons brought severed tendons together, corrected deformities designed corsets and apparatuses for orthopedic purposes, invented gold and silver tubes to be used after tracheotomy. Cabral declared wounds of the heart not necessarily fatal, Fioravanti reported a case of splenectomy with recovery. Berenger detailed some cases of *extirpatio uteri* for prolapse, and above all they did magnificent work in plastic surgery. They made new noses by shifting face flaps and also from the arm. Some of their names became infamous throughout Europe for daring to interfere with Providence in this way. When gunpowder came to be used they did some magnificent work on the treatment of bullet wounds. A series of experiments were made by Italians on this subject in the most thoroughly scientific temper. They demonstrated beyond all doubt that bullets did not

sear or burn tissues nor poison them. Biondo, a great Italian physician, described the treatment of wounds simply with warm water and without messy applications. He says that many surgical patients are not killed by their disease, but by starvation and the unfortunate applications made to their wounds. He declared that perhaps "it is preferable to die in accordance with accepted methods than to live empirically." Evidently the whole of asepsis was anticipated, but the world was not ready for it for another five hundred years.

In medicine the physicians of the time were at least as great as the surgeons. They were not the foolish believers in drugs as they are usually supposed to be, but thoroughly rational therapeutists. Mercuralis wrote the famous book which has gone through so many editions in many countries, "De Arte Gymnastica," in which he treats of all the manipulations and exercises by which curative results may be secured. He anticipated fully osteopathy and chiropraxis, but he did not limit his therapeutics to these external means. He was the greatest consultant physician of his time, taught at Padua, afterwards at Bologna, then at Pisa, and finally went to Rome as the physician to the Pope. In the next century Santorio greatly enlarged diagnostics in medicine by instruments. He was the first to make use of the thermometer and hydrometer, invented a sphygmometer, or, as he called it, a *pulsilogium* or pulse measure. He invented the trocar and cannula and used this for tracheotomy. He suggested a similar instrument for abdominal puncture. He made a bed bath for patients too weak to be lifted out. He counseled baths for patients suffering from hectic fever. He invented a bed with six different positions so that patients might be put at ease, their bed clothing changed, their meals given to them easily, besides contriving an arrangement for lifting the patient for transfer to another bed. Anyone who thinks that any of the modern inventors of surgical and medical beds have anything on Santorio ought to see some of the pictures that we have. He arranged a scale on which a man sat within an enclosed cell so that his metabolism might be measured, his food carefully estimated, and his excretions noted. This was most ingenious and yet wonderfully simple. You may see a picture of it in Garrison's History of Medicine.

All down the centuries since the Renaissance time the Italians have been leaders in surgery until the nineteenth century and even then they did not lag far behind, although there was so much political disturbance in the peninsula. The German, Gurlt, in his great history of surgery, devotes from three to five pages to each of nearly a score of Italian surgeons of the eighteenth century. Almost needless to say no one would be given this amount of space by the distinguished historian of surgery unless he had accomplished work that amply justified the distinction. The works of many of these men went into second and even to third editions and were known all over the medical world, for all physicians read Latin at that time and the usual course was written in Latin, and the Italians were the acknowledged leaders in the world's surgery of that time. In the nineteenth century Bassini, whose wonderfully well planned operation for the radical cure of hernia came to be known and practised all over the world, and Durante, who was one of the pioneers in the important department of the surgery of the central nervous system, carried on the tradition of great Italian surgery very worthily. In our time the Italians have remade—almost literally created the surgery of the heart. The stiletto rather than the revolver was the favorite weapon of the Italian bravo, and the surgeons at the Italian hospitals took advantage of this to study and treat wounds of the heart, until now it has come to be recognized that they are probably not so serious as wounds of the liver.

In the theory of medicine certainly the Italian authors are marvelous in their anticipation of details often thought modern. Benivieni, a simple practising physician at Florence, laid the foundation of pathological anatomy. Berengar first observed the appendix, Aranzi devoted special attention to tumors, Eustachius did much in pathology as well as physiology, Columbo, besides the pulmonary circulation, made a number of pathological observations, Fracastorio anticipated contagion, comparing it with fermentation; he invented the word syphilis and shares with Leonardo da Vinci the honor of being the first geologist to see fossils in their true light. The names of those who took up the doctrine of contagion makes a rather long list. Singer in London has shown how many of the Italians took up this task of developing the doctrine of contagion. Lancisi clearly grasped the relationship between gnats and malarial fever and Vallisnieri attributed the diseases of men and beasts to vermicules, thus anticipating modern bacteriology.

The Italian clinicians were wonderful observers. Vierordt, himself a distinguished contributor to the subject of heart disease, has named more than a dozen of men among the Italians of the seventeenth and eighteenth centuries who made important contributions to our knowledge of the heart in the last three or four centuries. Albertini and Valsalva in the eighteenth century outlined the rest and hunger cure for aneurysm. Lancisi and Morgagni traced aneurysms and other heart troubles to lues. The Italians described particularly nervous conditions of the heart. Santorio classified seventy-three kinds of pulse. Lancisi and Morgagni's work restored the balance of common sense and kept trivial details from being made too significant.

Galileo first hit on the idea of using his pulse beats to time the pendulum swing. From this developed pulse counting and temperature estimation. The Italians have taught us more about the intestinal parasites of man than anyone, and it was they who emphasized the great principle *omne vivum ex vivo*. Spontaneous generation continued to be believed, but not in Italy. The Italians were particularly forehanded in recognizing contagion and preventing it. They thought tuberculosis contagious and insisted on burning everything that had been touched by the consumptive, at a time when other nations were quite sure that it was hereditary and that the Italians were fools. In the modern time they have done much to prevent malaria and study its various forms and develop the knowledge of it. They were the first to have pharmacy gardens in connection with their medical schools

and hospitals and the botanical garden became a regular feature of the University life. They had them long before other places and were the exemplars in this matter. Very probably the best book over written on the prolongation of life and which contains most of the ideas to be found in many of the volumes on health preservation in modern times is Cornaro's little volume on a sober life, for that is what he called it, or how to live to be a hundred years. Cornaro found himself at the age of forty drifting into premature old age and threatened by the approach of death. He learned how to live and when he was past eighty wrote his book telling others how to do it, issuing the last edition of it when he was over a hundred years of age. The book has been published in all the important languages many times and has probably gone through more editions than any other book, except the famous "Regimen Sanitatis" of Salerno, the first book of popular medicine issued in modern times.

In the last two centuries Italians' names have rightly become associated with important contributions to medicine. Banti's disease is called after its Italian discoverer in deserved recognition of the fact that here was the finding of a special symptom complex after the most acute clinical observation, the varying parts of which had never been put together before. Often when diseases are called by the names of men of other nationalities the original discoverer was an Italian. Exophthalmic goiter is called Graves' or Basedow's disease, but long before the Irish physician called attention to heart palpitation with goiter and nearly fifty years before Basedow described the third symptom, the prominence of the eyeballs, the Roman physician Flajani had described the disease, and if any name should be associated with it it ought to be his. We have heard much of sleeping sickness in recent years, but Dr. Garrison, in his "History of Medicine," tells us that Castellani was the first to see trypanosomes in the spinal fluid and blood of five cases of African sleeping sickness. Italians have done much for trypanosomiasis generally. Negri's bodies in hydrophobia and Guarnieri's studies of *Cytoryctes variolæ*, possibly connecting protozoa with smallpox, as well as the independent work of Italians on spirochetes in African relapsing fever are all proofs of the pioneer quality of Italian medical power of observation. We have heard much of occupation diseases in recent years and the "safety-first" movement, but Ramazzini was the first to write a book on the subject and the Italians have worked out the subject of occupation diseases better than any others.

The most striking evidence as to the achievements of Italians in medicine is to be found in the number of structures named after Italians who discovered them. Here are a few of them, though I know that I by no means exhaust the list. There is the pons Varolii in the brain, the fissure of Rolando, the Vidian canal in the skull (named after Guido Guidi, Vidius in Latin), the duct of Botallo, a fetal structure in the neighborhood of the heart, the Eustachian tube, the Fallopian tube and the aqueduct of Fallopius, the organ of Corti in the ear and the rods of Corti in the retina, the Malpighian bodies in the spleen, the Malphighian corpuscles in the kidneys, and the rete Malpighi in the skin, Scarpa's triangle and the fascia and foramina called after him; and while Steno's duct is named after a Dane he made most of his studies down in Italy and acknowledged how much he owed to Italian opportunities for all that he did in anatomy. But this is only the beginning of the story as yet. There are in the larynx the cartilages of Santorini as well as emissary veins of the skull and the *musculus risorius*—the laughing muscle of the face named after him, and we have the ducts of Rivini, Ruffini's nerve endings in the skin, the spaces of Fontana, the sinus of Morgagni, the sinus of Valsalva as well as the functional connection between the throat and the ear, demonstrated by Valsalva's experiment and named after him, the process of Ingrassias, the band of Giacomini and the band of Gennari, the corpuscles of Pacini, the crescents of Gianuzzi, the Pacchionian bodies; there is the nerve of Lancisi, Golgi's processes of brain nerves and the organs of Golgi, the Casserian perforating nerve named after the great Italian surgeon, the foramen of Thebesio, the acqueductus Cotugni, through which the nasopalatine nerve described by Cotugno runs. Galvanism, named after Galvani, was discovered in the midst of medical experiments and Voltaic electricity deserves a mention here because it was discovered in connection with experiments and studies stimulated by Galvani's work.

There are other structures that bear the names of men of other nationalities that were really discovered by Italians. The sutural bones in the skull known as Wormian bones after Claus Worm, had already been seen, described, and even pictured by Eustachius. The duct of Wharton, so-called, had been described fully by Achillini. Piccolomini recognized the special character of the pancreas, and Eustachius described the capsule of Glisson, though this came to be named after an English anatomist who described it much later. Eustachius also described the renal tubules though these had been seen by Fallopius before and came to be named after Bellini. The duct of Wirsung was discovered in Vesalius' dissecting room by his prosector, George Wirsung. Scultetus and Spigelius, after whom the reverse mode of bandaging is named and the Spigelian lobe of the liver, were both students of Padus. I have attributed the discovery of the circulation of the blood to the Italians without wishing to impair Harvey's merit in the least and anyone who may think that that is due to over enthusiasm for the Italians should read Professor Foster's lectures on the history of physiology as they were delivered before a series of universities in this country. He did not hesitate to say "We must therefore admit that Caesalpinus had not only clearly grasped the pulmonary circulation, but had also laid hold of the systemic circulation; he recognized that the flow of blood from the tissues took place by the arteries and by the arteries alone, and that the return of the blood from the tissues took place by the veins and not by the arteries."

Is it any wonder that I should claim for the Italians a corresponding place in the history of medicine that the peninsula has admittedly in art and the arts? Yet I have told but a little of the story; the whole of it would fill volumes and has actually done so.

110 West Seventy-fourth Street.

HISTORY OF ALCOHOL AS A SUBSTANCE FOR HUMAN CONSUMPTION.*

By JOHN C. HEMMETER, M.D.,

BALTIMORE, MD.

PROFESSOR IN THE UNIVERSITY OF MARYLAND.

THE word "alcohol" comes from two Arabic terms, al, which is the article, corresponding to "the," and *kahal*, meaning a finely divided powder.

Originally, alcohol was the term applied to any finely divided body, but later became applied to the spirit of wine, after it had been brought to its greatest purification. Kopp, in his Geschichte d. Chemie, 1847, IV Part. p. 271, narrates that with the Arabians and also Spaniards, the word alcohol means antimonium sulphate—and not the C_2H_6O, but that the volatile part of wine was rendered freer from H_2O by placing it in contact with tartrates (Wein Steinsalz) and all salts are called "alcali" —thence was derived the term *spiritus alcalisatus* —which was corrupted into *spiritus alcolisatus*, and this word went over into *alcool spiritus vini*.

The ancients had no intimate knowledge of alcohol as such, although they consumed wine and beer. Their distillation apparatuses were too imperfect. The distillation apparatus was first introduced by the Alexandrians.

In 950 the Arabic physician, Rhazes, described a method of preparing alcohol, but does not mention its combustibility. In 1440 Giovanni Mick-Savonarola pubilshed a method of testing brandy for the amount of C_2H_6O. In 1784 Lavoisier demonstrated the composition of C_2H_6O. In 1784, Carl Wilk Scheele showed that when C_2H_6O and organic acids form ether, this ether can reversely be converted into the acid and C_2H_6O used. In 1796, absolute alcohol was made by Tobias Lowitz with dehydrated (freshly heated) calcium carbonate.

Adherents of alcoholic beverages frequently maintain that the use of alcohol like that of all other stimulants is due to a deep-seated necessity of the human race. Alfred Grotjahn, in the thirteenth volume of the Library of Social Sciences (Bibliothek der Socialwissenschaften), which appeared in 1898, makes the assertion that the desire for alcoholic beverages has for all time been so general with all peoples that the same must be regarded as a common human heritage. Older authors speak in the same strain. Even Pappenheim asserts in his work, "Sanitätspolizei," that alcoholic beverages seem to have been evolved to meet an ever-present requirement of the human race. We can only hope to do away with inebriety and the stronger alcoholic mixtures.

In contravention to this, Baer states in his standard work: "The human race surely has existed countless ages without using these artificial remedies. Many races exist to-day or have lived recently who developed no feeling of instinctive necessity for these things until they became cognizant of them."

I have made it my business to show that the whole alcoholic question is the product of a very slow process of evolution from a very modest beginning to its present proportions, from a slight inclination to its subsequent abuse.

*Read at the annual meeting of the American Therapeutic Society, June 3, 1921. (See page 300.)

From prehistoric times to which the historic period compares as a small fraction of time, no clue has come down to us in regard to the use of alcohol. Man could only consume that which nature voluntarily offered him. Very gradually did he develop his customs and his tastes through learning to adapt the forces of nature to his purposes.

As glorious as this victory of consciousness over subconsciousness really was, it brought with it many customs and habits which, being in opposition to the laws of nature, superinduced sickness, misery, and crime. As the prime offender we have the consumption of alcoholic beverages. Their first appearance is enshrouded in mystery. The first mixtures of sweet wines and other fermented beverages with much water had doubtless an agreeable effect, as well as the ensuing mild paralysis, which revealed itself as a heat sensation and a stressing of the emotional propensities of the individual.

Tolstoi maintains that the chief objective of alcohol consumption is the paralysis of the conscience. If these primitive people had been aware that the aforesaid phenomena of paralysis were in fact symptoms of poisoning, and had had some knowledge of the concomitant and after effects of same, they would have been still more cautious than they really were with their discovery. Thousands of years after the first production of wine it was used in small quantities, highly diluted, in conjunction with meals. Among the Israelites, who were the first to produce wine, drunkenness was not known to any extent.

The Israelites preserved their wines in skins and jugs. The German, French, English, Italian, Latin, and Greek words for wine are derived from the Hebrew "yain." Wine was used with meals and for devotional purposes. There was no abuse, and hence Moses saw no necessity to formulate regulations in regard to its consumption. The Semitic peoples, more particularly the Phoenicians, introduced wine to all the Mediterranean nations, of which we shall refer especially to Egypt and to Greece. To be sure, the Egyptians had concocted a drink from barley and bitter herbs and the Greeks had done the same through the fermentation of dates, figs, apples, and honey, but wine rapidly supplanted these.

It is necessary to emphasize that such a thing as drinking apart from meals, and also the existence of inns, was out of the question. The Greeks were the first to use wine not as an adjunct to meals, but at entertainments devoted to sensual enjoyment. They consumed wine greatly diluted with water, while listening to the music of the flute and kithara, while nude female slaves danced and sweet smelling odors permeated the halls. Rough, boisterous conduct at these affairs was regarded as beneath contempt, barbaric. There was no drinking in the open or at political gatherings, gymnasiums, or baths.

Greek emigrants introduced the manufacture of wine into Sicily and Italy. Wine rapidly supplanted the fermented brews of barley and honey of the Romans. It thrived everywhere on the peninsula, was diluted with sea-water and consumed at meals. At first drinking by women and young men was discountenanced; but very gradually, near the end of the imperial period, women took up drinking.

The feeling was about the same as is now that regarding smoking by women.

When intemperance had become a fact, particularly with the well-to-do classes, the first measure against the use of wine was called into existence by Domitian (87-96 A.D.). Domitian forbade the development of new vineyards and ordered the demolition of one-half of those in existence. This regulation remained in force 200 years. It was annulled by the Emperor Probus (276-282 A.D.).

Rome's historians and moralists do not make any references to alcoholic abuses of the middle and lower strata of society. We can assume, therefore, that in the case of the ancient peoples, there was really no alcoholic question. This first sprung into existence when the Romans came in contact with the barbarians. Just as happens to-day, when a highly civilized people introduces a narcotic to a savage people, the foreign nations, such as the Scythians, Thracians, Macedonians, Gauls, and the Germanic tribes adopted wine with avidity, drinking it unadulterated. Nearly all terms pertaining to the raising and making of wine may be recognized as Latin derivatives.

Although the Teutons, like the Egyptians, Greeks, and Romans, had a mildly intoxicating drink, derived from honey and called meeth, it is, nevertheless, very improbable, at any rate not demonstrable, that they produced the same in large quantities, as the art of husbandry was not developed to any extent with them.

With reference to the frequently cited passage in Tacitus' "De More Germanorum" 22, 23, that Teutonic armies suffered defeats owing to widespread drunkenness, let it be said that these occurrences were not, as is frequently assumed, the result of an inherited trait, but a phenomenon corresponding exactly to the effect of spirituous liquors on American and African indigenous tribes.

Some Teutonic tribes evidently recognized the great danger of the new drink (for which see Cæsar's "De Bello Gallico" Liber 4, Chap. 2), where the Suevi are reported to have instituted measures prohibiting the importation of wine.

After the fall of the empire the barbaric custom of drinking unadulterated wine to the point of intoxication, spread through Europe. Such was the state of affairs during the time of the racial migrations. Christianity might have been an effective check to the growing alcoholism, but unfortunately, several centuries had elapsed since Christ had first offered his doctrines to the world. In His time the drink habit was of such insignificance that there was just as little reason with Him as had been the case with Moses, to agitate against it. With the third religious founder, Mohammed, things were different. In his time the drink habit had reached such proportions that he started the greatest anti-alcohol movement known up to that time, and succeeding in eradicating wine growing in all conquered regions.

A peculiar accident would have it that Mohammedans, that is, Arabian physicians, succeeded in the eighth century in distilling brandy from wine, which discovery was to be devoted to healing purposes. They called the new product *al kohol*, that is, "fine extract." It was a very unfortunate incident, insofar as it encouraged to an enormous extent, the abuse of alcohol. Later on, Occidental alchemists took possession of the newly acquired knowledge. After repeated distillations, that is, rectification, a more concentrated spirituous liquor was obtained until finally Basilius Valentinus, a Benedictine monk, succeeded in producing an almost pure alcohol. The belief spread that this wonderful thing, "spiritus vini," was an all cure remedy for diseases and also a preventive agent against epidemics, such as the pest.

Michael Schrick. in the year 1482, at Ulm, offered this precept in his work, entitled "The Burnt-out Waters," published at said time and place: "Whoever drinks one-half spoonful of burnt wine every morning, will never become sick." The price of this "burnt wine," however, was so high at that time that only the well-to-do classes could carry out the suggestion.

In the meantime, wine culture developed northward up to the limits set by the climate itself, that is Central Germany. In North Germany, after the Teutons had developed their knowledge of agriculture, there was produced an alcoholic stimulant from barley, which was called in Anglo-Saxon "bere." This was also done in northern Gaul.

In the twelfth century, John the First of Flanders and Brabant, known as Jan Primus, became such a patron of the brewer's art at Bruges, that he evolves later into Gambrinus, the legendary patron saint of the brewing industry. In the fifteenth century, the art of brewing made a marked advance when it acquired knowledge of the malting process, succeeding in making a much more palatable and stable beer than was known before, particularly in Einsbeck, Naumburg, Hamburg, and Brunswick.

With growing wealth and consequent luxury, debauchery and intemperance became always worse, so that Emperor Maximilian the First at various diets from 1495 to 1512, took a most decided stand against the drinking habits of the well-to-do classes. About 1600 the first temperance society was founded. The members of this society had to agree not to drink more than fourteen goblets of wine a day.

A new advance in the technique of making spirituous liquors made the latter accessible to the lower social classes. It was the manufacture of brandy directly from corn. This discovery made in the sixteenth century was spread everywhere, into the smallest hamlets, by the soldiers during the Thirty Years' War.

Duke Ernst August, in 1691, expresses his great regret in an edict that spirituous liquors which were really intended for purposes of healing had become an instrument of debauchery, and that even in the places where they could be bought, drinking rooms existed in which such debaucheries were carried on.

The wrong assumption that spirituous liquors gave strength and health wa slargely responsible for the diffusion of the custom. In Hungary in 1550 miners regularly received apportionments of alcoholic stimulants to increase their efficiency. Soon after this, the beginning of the drink tip, or "trinkgeld," as it is called, makes its appearance, supplanting the bath tip. In the fifteenth century every village in Germany and Austria had its pub-

lic bathhouse from which was developed later the barber shop. Apprentices and servants received on Saturdays and on the days preceding holidays, the bath tip. In the course of time the opinion became current that pest and syphilis, which had been imported from France, were transmitted in the bath rooms. Spirituous liquors were regarded as preventives of these dread diseases, and thus the drink tip replaced the bath tip.

As the manufacture of spirituous liquors became cheaper and cheaper, the demand for them increased and in consequence the injurious effects became worse. Perhaps it was necessary to have the whole matter reach such enormous dimensions as to make the necessity for calling a halt seem more imperative.

In reply to such writers who care to assert that the drinking habit is really the result of an inherent instinct, I shall refer them to this assertion from Darwin's pen, to the effect that since an acquired habit becomes hereditary, the similarity between an acquired habit and an instinctive trait is so great that the one is not susceptible to differentiation from the other.

To the impartial observer who can follow the development with an unbiased eye, it would appear that this gradually expanded habit was not instinct at all. I believe that all drinking customs to the contrary notwithstanding, the opinion which the great Dutch savant Donders expressed in the year 1853, in his work entitled "Foodstuffs," still holds good, to wit, "If from to-day on not a drop of spirituous liquor is consumed, the instinct will become after a few generations dormant, if not entirely eradicated."

THE PHARMACOLOGY OF ALCOHOL AND ITS INFLUENCE ON METABOLISM.*

By JACOB DINER, M.D.,

New York.

"What wonders does not Wine! It discloses secrets; ratifies and confirms our hopes; thrusts the coward forth to battle; eases the anxious mind of its burden; instructs in arts. Whom has not a cheerful glass made eloquent! Whom not quite free and easy from pinching poverty!" Thus spoke Horace. When we speak of alcohol we are understood to refer particularly to the so-called grain alcohol, C_2H_5OH. Yet would we fail in our undertaking if no reference, though passing, were made to other alcohols which are included in the series of this type of hydrocarbon compounds and which, according to Baer, show a toxicity progressing with the n — value of the compound. Thus he finds:

Alcohol	Formula	Toxicity
Methyl	CH_3OH	0.8
Ethyl	C_2H_5OH	1.0
Propyl	C_3H_7OH	2.0
Butyl	C_4H_9OH	3.0
Amyl	$C_5H_{11}OH$	4.0

Or, taking the later figures of Macht, and of Morgan and Cooper, and Kamm, we find the following:

Alcohol	Macht Toxicity to Cats	Morgan and Cooper Germicidal Power	Kamm Toxicity to Paramecia	Albumin Coagulating Power
Methyl	0.8	0.95	0.8	0.9
Ethyl	1.0	1.0	1.0	1.0
n-Propyl	2.5	2.5	1.9	2.0
n-Butyl	16.6	8.0	4.5	5.0

*Read at the annual meeting of the American Therapeutic Society, June 3, 1921. (See page 300.)

However I will limit myself, in the further discussion of this subject, to ethyl alcohol only.

Forms.—Alcohol is official in the United States Pharmacopoeia in three forms: Alcohol, 92.3 per cent. by weight of C_2H_5OH. Alcohol dehydratum, 99 per cent. by weight. Alcohol dilutum, 41-42 per cent. of weight.

To these may be added the various forms of galenical preparations which contain alcohol either as menstrum, solvent or preservative, such as the elixirs, spirits, tinctures, fluid extracts, etc.

The substances from which alcohol is obtained are too numerous to mention. Suffice it to say that almost any carbohydrate, under proper conditions of treatment — fermentation — will yield alcohol. The non-official forms of alcohol (some of these are official in other countries) are:

A. Whiskey. This is obtained by the distillation of the mash of fermented grain, with an alcohol content of from 46 to 55 per cent. (vol.).

B. Brandy (also known as Cognac). A distillate from fermented juice of grapes, with an alcohol content approximately the same as that of whiskey.

C. Wines. (*a*) White and red wine—according to whether the skin is excluded or included—are non-distilled beverages, the product of fermentation of grape juice, with alcohol content of 10 to 15 per cent. (*b*) Sherry and port, similar origin to above, with alcohol percentage of from 15 to 25 per cent.

D. Ciders. Fermented liquors obtained from fruit other than grapes. Alcohol percentage, 5 to 10 per cent.

E. Malt liquors, containing, in addition to alcohol (2 to 6 per cent.), more or less sugar, CO_2, and hops.

F. Fermented milk, known as kumyss, about 3 per cent. alcohol.

Among the less known alcoholic beverages may be mentioned:

G. Small beer, 1.5 per cent.; brown stout, 6.5 per cent.; bitter and strong ale, 10 per cent.; Chica, or Indian corn beer, a drink of South America; Bouza, or millet beer, also known as murna—used by Crimean Tartars; Quarf, or rye beer, a Russian drink; ava, cava, or arva, prepared from the root of long pepper; formerly used in the South-sea Islands, all along the Pacific Ocean, Tahiti, Sandwich Islands, and Fiji Islands.

A great deal has been said and written with reference to the constitution of the substances that give wine its flavor. This matter is involved in considerable obscurity and the greatest differences of opinion obtain. According to older writers and investigators there is one aromatic substance present in all wines; this substance is known as œnanthic ether, $C_2H_5C_7H_{13}O_2$. Other aromatic substances present in wine are: ethyl acetate (acetic ether), $C_2H_5C_2H_3O_2$, developed in wine by age and frequently added for the purpose of adulteration to simulate age in wine and to improve the "bouquet." Butyric ether, or rather the esters thereof, ($C_2H_5C_4H_7O_2$), and caprylic ether ($C_2H_5C_8H_{15}O_2$), both of which have a fragrance resembling pineapple, are also employed for similar purposes. A variation of the bouquet may also be produced artificially by any of the following ethers: caproic, pellargonic, capric, proprionic, amylic, and many others.

Plants, such as rose leaves, lime and elder flowers,

leaves of the meadow sweets, peel of the quince pear, blossoms of wild vines, sage leaves, violet roots, and many others are also used to increase the bouquet of different wines.

According to more modern investigators the different bouquets are dependent upon the differences in the yeasts infesting the grapes. So, for instance, the inoculation of a barley infusion with a wine yeast give the fermented liquid the peculiar flavor of that particular wine.

Generally speaking, we may say that the chief and only difference in the different alcoholic liquors is in the substances from which the mash is made.

Liqueurs, cordials, and bitters, running in alcoholic content from vermouth (17 per cent.) to absinthe and benedictine (55 per cent.), are made by mixing fragrant herbs with alcohol or wine and either macerating or distilling.

Mode of Administration.—Alcohol has been administered practically, in every manner known to medicine, excepting perhaps the intravenous method.

Pharmacology.—Inasmuch as provision has been made in our symposium for detailed discussion of the effect of alcohol on the individual organs and tissues, I will but briefly touch upon its pharmacological action.

The Cell.—Upon the individual cell it acts as a protoplasmic poison, interfering with the oxidation of the tissues and leading to fatty degeneration. It is also said to diminish the resistance to acute and specific diseases, to lessen phagocytosis, and to interfere with the development of immunity.

Central Nervous System.—While alcohol has been considered a stimulant to this system, modern investigation necessarily leads us to a contrary conclusion. We must concede to the brain the functions of control and inhibition. When, under the influence of alcohol a depression of the higher centers is produced, it can readily be understood that the incoordinate, nonconcentrated, and therefore planlessly exaggerated reactions of the more resistant deeper nerve centers (basal ganglia) will become more pronounced and more prominent. The popular saying "that alcohol loosens the tongue," in my opinion summarizes this in a very concise manner. The phenomena quoted from Horace at the beginning of my paper are clearly the manifestations of a loss of inhibition rather than of cerebral stimulation. The ready flow of unbridled speech, the boisterous, often offensive laughter, readily changed to crying, the sudden bursts of temper or even violence cannot be interpreted otherwise.

On the other hand it has been demonstrated that small amounts of alcohol will increase motor efficiency to a considerable extent. This again has been held by some (Kraepelin and others) to be direct evidence of a stimulating effect, while the opponents (Lombard, Meyer and Gottlieb, and others) bring this forward as an additional proof of inhibition of the higher centers. Schmiederberg sides with the latter group and maintains positively that "Alcohol is not a stimulant but a depressant"; that, "in the mental areas the finer degrees of observation, judgment, and reflection are the first to disappear."

Nerves.—Götch, in Schäfer's Physiology, quotes experiments of Piotrowsky on the effect of alcohol on the excitability and conductivity of nerves: Alcoholic vapor caused an initial increase in the local excitability and, to a less extent, in conductivity. This soon changed, the conductivity becoming rapidly impaired before the local excitability diminished; on the cessation of alcoholic vapor, the normal conductivity and excitability were reinstated, the latter returning quicker than the former. The reaction time was also increased by alcohol.

Respiration.—A distinct "stimulating" effect on the respiration can be credited to alcohol, probably directly due to stimulation of the respiratory center. The volume of the respiration and, as a result thereof, the quantity of exchanged air are increased; the respiratory increase from alcohol is noticeable even during sleep.

Circulation.—If one or two ounces of brandy (about 50 per cent. alcohol), well diluted, be slowly swallowed the pulse is slightly quickened; there may be a temporary constriction of the splanchnic vessels and a slight rise in blood pressure. All this is probably due to the irritating action upon the nerves of the stomach. After absorption it has a paretic effect on the vasomotor system with a resulting drop in blood pressure. The effect is general but is especially marked in the nerves and vessels of skin and muscles, causing a rush of blood to the surface. The vessels lose their thermo-accommodation power and consequently there is a large cooling surface which allows of a rapid lowering of temperature, other conditions being favorable. Because of its direct action as a protoplasmic poison on the muscular fibers of the vessels and its paretic effect on the vasomotor nervous system it has a dilating effect on arterioles and arteries, and a similar, though less marked, effect on the heart itself. This causes a lowering of blood pressure, diminution of systolic output from the heart, and the cardiac energy is wasted, pumping blood into relaxed vessels. The large bounding pulse, with comparatively shorter systole, which gives a deceptive appearance of vigor and force to the circulation, is due to the large wave in the dilated vessels. The venous and diastolic pressure within the heart are temporarily increased. According to Dixon in small quantities and in concentrated form alcohol quickens the pulse, constricts the deeper vessels, increases the blood pressure, especially when the heart action is feeble, and is therefore of great service in fainting. In too large doses he considers it as a distinct depressant to the heart.

Metabolism.—Many and conflicting views have been advanced regarding its value as a food, and its influence on metabolism. Neubauer has observed that in severe diabetes mellitus it may be used to check the output of acetone. Atwater and Benedict have shown that the efficiency of alcohol in the protection of body fat is as marked as that of fats and carbohydrates, and somewhat less than its protein saving and protecting power. Experiments have shown that alcohol, prior to its combustion in the body, exerts a notable influence upon the metabolic processes of the liver, and possibly in other organs, whereby a marked effect is produced upon the output of uric acid.

When taken with purin-containing foodstuffs it exerts a direct influence upon the metabolism of those compounds which give rise to exogenous uric

acid, increasing largely the amount of uric acid excreted. It therefore cannot be rated as a true non-nitrogenous food in the sense in which fats and carbohydrates are foods.

Experimental: Heart.—After ascertaining the normal rate of the pulse on 62 students the class was divided into three groups: To group 1, no alcohol was administered; to group 2, 4 c.c. of alcohol was given; to group 3, 15 c.c. of alcohol was given. In each case the alcohol was administered in 120 c.c. of water, group 1 receiving 120 c.c. of water alone, so that none of the students were aware what medication, if any, was administered. Group 3 showed an increase in the rate of the pulse averaging 12.5 beats per minute. Group 2 showed a decrease of the rate averaging 8 beats. Group 1 showed no variation. The effect was noticed within 15 minutes after administration of the drug and lasted for 20 minutes after the first effect was noticed.

Cerebrum.—The same procedure was followed as above, at a subsequent session. The same quantity was administered. Before beginning the experiment three simple mathematical examples were dictated to the students. One example was a simple addition of figures, one a division and the third a multiplication.

At a given signal the students began their work and were again stopped at a signal. Ninety-eight per cent. of the students finished all the tasks and 87 per cent. of those finishing were correct. After a short wait the alcohol and, to group 1 the water without alcohol, was administered. Ten minutes after administration the signal was given to begin work, three examples exactly similar in every way to those previously given were undertaken and the work stopped as before, within the same time limit. All of the men receiving the alcohol had finished the work in the time allotted. Ninety-seven per cent. of those having received the water were finished. Of those receiving the alcohol the results were as follows:

Group 2. (4 c.c.), 78 per cent. were correct.

Group 3 (15 c.c.), 62 per cent. were correct.

Conclusions: Alcohol caused a quicker response but at the expense of accuracy.

Metabolism.—Four patients with diabetes mellitus were daily examined as to percentage of blood sugar. One showed acetone in the urine and all had an increased blood sugar content. After administration of 4 c.c. alcohol for 8 days the percentage of blood sugar decreased in all patients, the diet remaining the same. The blood sugar (Lewis & Benedict method) ran from 0.135 to 0.413 before alcohol was administered and sank to 0.135-0.168 respectively.

	Before.	At end of exp.
Case 1	0.182	0.135
Case 2	0.413	0.159
Case 3	0.357	0.168
Case 4	0.284	0.162

Whatever the evidence of the laboratory may be, however, we must bear in mind that in the final accounting we have to consider this as a drug and its action in pathological and not under normal conditions. And here the final word belongs to the man who makes his observation at the bedside.

May I therefore quote, as my concluding sentiment, from one of the keenest observers and clinicians, our late Abraham Jacobi, "I do not care to classify alcohol anywhere. I do not contest observations and experiments on either healthy or diseased men and on animals. . . . One of the most profitable laboratories, however, is the hospital and the private bedside." . . . And there he found alcohol a valuable remedy.

Great clinicians are more circumspect than loud. Hippocrates says more frequently than any of his successors, "It seems to me."

THE EFFECT OF ALCOHOL ON THE GASTROINTESTINAL TRACT.*

BY WILLIAM J. MALLORY, A.M., M.D.,

WASHINGTON, D. C.

ASSOCIATE IN MEDICINE, GEORGE WASHINGTON UNIVERSITY MEDICAL SCHOOL.

IN the discussion of any subject it will be noted that erroneous ideas are due to two principal causes: first, the ignorance of facts, and second, ignorance of the relation of facts to the problem under consideration. Error arising out of gross ignorance is usually comparatively innocent and harmless, as compared with that brought about as a result of a misinterpretation or misuse of known facts.

This, I believe, is especially true in the domain of medicine, and more particularly in experimental physiology, pharmacology, and therapeutics. We see experiments made upon herbivora and the deductions applied to omnivora; observations on the normal applied to the abnormal, and vice versa. The voluminous data on the physiological and pathological effects of alcohol on the human organism are no exception to this general statement, but an excellent example. This is so notorious that the discussion of the subject provokes a smile, if not ridicule.

The mention of alcohol brings up ideas concerning its industrial, economic, social, political,

*Read before the American Therapeutic Association / its annual meeting, June 3, 1921. (See page 300.)

and sometimes its physiological relations, and last and least of all, its therapeutic application; and in the discussion the ideas become so mixed that the truth on any one point is usually obscured or missed altogether. It is, therefore, especially necessary that one should be very explicit in stating what aspect of the subject is to be discussed and in what domain the deductions are to be applied.

The title, "The Effect of Alcohol on the Gastrointestinal Tract," should convey the following definite ideas: 1, Therapeutic preparation; 2, therapeutic doses; 3, administered in disease; 4, diagnosed by a physician.

This should exclude many data and many ideas which have no bearing on the aspect of the question under discussion, but it does not always do so, for we see advocated the proposition that alcohol should be excluded from the pharmacopeia, and the reasons given such that, if valid, they would be equally applicable to such drugs as mercury, bromide, belladonna, and opium; for mercury in large doses is an irritant to the gastrointestinal tract, kidneys, liver, and central nervous system; bromide impairs mental accuracy and physical efficiency; belladonna in large doses will produce an active, talkative delirium, and opium is a habit-forming narcotic.

Although some of the physiological experiments have been made with pure alcohol diluted with water, it is needless to state that it is practically never used internally for therapeutic purposes in this form, but as wines, beer, brandy, whiskey, liqueurs, and cordials, and as a solvent for various drugs.

Taking up the effects on the digestive tract in the order in which they are produced, we have first the sensory effects. Here at the very beginning we are face to face with the specific application of a fact of fundamental importance and general application, namely, that it is impossible to discuss therapeutics intelligently without referring to physiology, for it is through sight, smell, taste, and physical contact that alcoholic preparations produce their sensory effects on the digestive tract which must be summed up under the term appetite.[1] Now, appetite and hunger are not, as many suppose, different degrees of the same sensation. They are fundamentally different; that is, they differ in quality, for hunger is essentially an epigastric sensation of varying degrees of discomfort or pain, definitely associated with the characteristic hunger contractions of the stomach, while appetite for food is a much more intricate complex, an emotion.

While a certain sensation complex from the viscera and an approximately normal state of central correlation constitute a necessary background for the development of appetite, the condition itself is essentially a complex psychic state, or emotion, aroused by the action of sensory stimuli having pleasant memory associations with past experience.

To describe the steps by which a sparkling glass or foaming mug stimulates the appetite would be pedantic. The increased flow of saliva and the swallowing movements induced by visual memory alone speak convincingly. The stimulation of the olfactory nerves by the aroma acts in a similar manner, no less effective.

The taste of pure alcohol, or the same diluted with water, is not especially appetizing, but the alcoholic beverages containing aromatic substances from the grapes, ethers, esters, etc., or the malt drinks act through the end organs of taste to increase appetite.

The physiologist Carlson states:[2] "The writer is neither a total abstainer nor a habitual user of alcoholic beverages. But it is his experience that a glass of beer taken at meal time seems to awaken or increase appetite. The effect is rather immediate and therefore not due solely to the absorption of the alcohol. Pavlov has recorded an instance from his own experience where a drink of wine seemed to initiate the sensation of hunger the very minute the wine reached the stomach."

In addition to the above mentioned action of such beverages through sight, smell, taste, and directly on the gastric mucosa, there is another important method of action.

Hunger may be present with all its qualms, and accessory phenomena of lassitude, weakness, nervous irritability, and vasomotor instability without appetite for food. Unpleasant emotions, anxiety, depression, or mental fatigue usually inhibit the appetite even when hunger and need of food are present. Under such conditions a moderate dose of alcohol when absorbed acts on the higher psychic centers in such a manner that inhibition is relaxed, the emotions released, and there is a pleasant physical and mental relaxation with a feeling of ease and comfort during which inhibited appetite returns. Overdosage may destroy appetite just as overeating of the most harmless food will produce a feeling of revulsion, and even digestive disturbance or disease.

On the secretory function alcohol causes a temporary increase in the outflow from the glands, but no permanent increase in production.[3] It is therefore a negligible factor in its action on the secretion. After absorption, even from the rectum, it increases gastric secretion.

On the ferments, minute quantities, not over 2 per cent., slightly accelerate the action under experimental conditions. Larger amounts, of from 5 to 10 per cent., slightly retard proteolytic action.

Foods are unaffected in the stomach, with the exception of proteins, which are coagulated or precipitated if in solution, which is a preliminary step in digestion.

In the preparation of foods, especially eggs, milk, and sauces, it increases their palatability and digestibility and adds to their nutrient value.

Alcohol and alcoholic solutions are absorbed from the stomach more rapidly and to a greater degree than any other substances.[4] The rate of absorption depends very greatly upon the amount and character of other substances present in the stomach. For example, milk is the most effective foodstuff for delaying the absorption of alcohol into the blood, and this is almost equally effective whether mixed with the alcohol at the time of drinking, or drunk two hours before the alcohol. Fats inhibit its absorption, especially when in strong solution. Other foods have very slight effect in this respect.

The relative amounts of alcohol absorbed from the stomach and the intestine naturally vary very greatly with such conditions as the character and amount of foods in the stomach and the rapidity of evacuation. This is, however, a matter of little practical importance since the drainage in each case is to the liver.

On the motor function of the stomach it acts as a carminative, that is, it arrests or modifies excessive contractions, without inhibiting normal motility. As a result of his most accurate experiments on the motor functions of the stomach, Carlson states:[2] "Tests were made with sour and sweet wines, brandy, beer and pure alcohol diluted with water. * * * In view of the fact [already stated, that alcoholic drinks promote appetite] we expected to find that these alcoholic beverages increased the tonus and the contractions of the empty stomach, since it is the tonus and the contractions of the empty stomach that give rise to the hunger sensation. To our surprise the results proved to be the very opposite. Wine, beer, brandy, and pure alcohol (diluted) introduced directly into the stomach inhibit the hunger contractions and the tonus of the empty stomach instead of increasing them. * * * In other words, alcoholic beverages when introduced directly into the empty stomach in quantities and concentrations that directly affect the tonus and the contractions of the stomach cause inhibition, and inhibition only. * * * The duration of the alcohol inhibition varies directly with the quantity and concentration of the beverage introduced into the stomach. Thus, 50 to 100 c.c. of 10 per cent. alcohol may inhibit the hunger contractions for 1 to 2 hours; or, if introduced during a period of relative quiescence, it delays correspondingly the onset of the next hunger period. Inhibition for 30 to 60 minutes is caused by 200 c.c. of beer. The sour wines on the whole cause greater inhibition than the sweet wines, probably through their acids. * * * If alcoholic beverages in the stomach caused as marked inhibition of the stomach movements in digestion as they do in the stomach movements in hunger, even moderate drinking with meals would lead to acute indigestion. As this is not the case, it is evident that alcoholic beverages affect the mechanism of these two types of movement differently."

The unpleasant emotional states of anxiety, depression, or mental fatigue which inhibit appetite have been shown by both experiment and clinical experience to impair gastric motility. Under such conditions alcohol absorbed acts upon the higher nerve centers, producing inhibition, relaxation, and mental ease, with resulting improvement in the gastric condition and restoration of normal motor function.

From the facts presented and their relation to human physiology, it is a reasonable deduction that alcoholic beverages have certain practical application in the treatment of diseases in which it is desired to influence the gastrointestinal tract. Therapeutic use and contraindication must be determined here as elsewhere by the physician who has diagnosed the particular case, but a statement of certain principles, with examples of application may be given.

In any case where it is desired to awaken or stimulate the appetite, one of the wines or malted drinks would be an aid, and the dose of the beverage used for such a purpose would not contain a sufficient quantity of alcohol to fall under any of the contraindications hereafter mentioned.

In conditions of hypermotility of the stomach, due to mental unrest, anxiety, or worry, accompanied by a feeling of epigastric discomfort, fullness, and distention or tightness, alcoholic beverages, as above stated, act both locally and after absorption on the mechanism involved; namely, inhibiting excessive contractions when introduced into the stomach, and when absorbed acting on the central nervous system, producing psychic relaxation, which, if not removing the cause, at least makes it ineffective.

While a drink of whiskey or beer will allay the pains of gastric ulcer or pylorospasm, its use in these conditions as well as in all other conditions requiring surgical treatment is not rational.

Alcoholic beverages should not be used as a stimulant in cases of nausea, vomiting, and shock when the condition may be due to the presence of unknown toxic substances in the digestive tract, because they generally increase the absorption of certain substances and would therefore increase the systemic effects of the poison.

EFFECT OF ALCOHOL IN THE THERAPY OF INTERNAL DISEASES.*

By CHARLES G. STOCKTON, M.D.,
Buffalo, N. Y.

It is probable that over the action of no single therapeutic agent has there been more acrimonious and combative discussion than over that of alcohol, owing to the contentions arising from its use as a beverage. This paper seeks to avoid the discussion of alcohol from any other than the therapeutic standpoint and as relates to general disease.

As a remedy, probably it has been more widely employed than any other agent, and until recent times the great importance of this use was unquestioned. The action looking toward the exclusion from the pharmacopeia of alcohol as a remedy probably fails to represent the opinion of the majority of physicians. The action of the House of Delegates of the American Medical Association on this subject makes it advisable for the American Therapeutic Society to review the subject thoughtfully, avoiding if possible the acrimony which heated debate often engenders.

A conservative examination of the question is

*Read at a meeting of the American Therapeutic Society, June 3, 1921. (See page 300.)

convincing that any substance so potent as alcohol, used so widely and indiscriminately in the treatment of all manner of diseases and symptoms, must necessarily have been harmful to many. Its supposed happy effect in many instances results from its dulling influence upon the nervous system and the temporary relief to mental and physical suffering. All will admit that to obscure a symptom is not necessarily desirable. Also it will be conceded that to charge the metabolism with the burden of dealing with assimilation and dissimilation of alcohol may at times prove an embarrassment to physiological activity and be a source of injury to the parenchyma of organs. Because of these and other possibly harmful effects, it has been asserted that alcohol is always a poison, and has no place in legitimate medicine. That such a decision is inconsiderate, partisan, and unsafe, I think there can be no doubt. The arguments advanced against the therapeutic use of alcohol might be raised as justly against the employment of any really powerful drug. Because it is competent to do harm is no reason that it is not competent to do good.

Alcohol as a Nutrient.—In considering its field of usefulness in general medicine, we cannot omit its importance as a substitute for food. By giving alcohol we often tide the patient over a critical period when other means of sustenance fail. To deny this is unreasonable. This is true in gastrointestinal diseases when there is faulty assimilation. When from exhaustion the digestive apparatus is so far crippled that it cannot digest or absorb the required amount of other forms of food, the administration of brandy, whiskey, or wine will save life, and to omit it approaches criminal neglect.

In diabetes, when it is incumbent to lessen the caloric intake of carbohydrates or of fats, or of both, alcohol in a certain class of cases serves an excellent purpose; nothing else can replace it. This is true at times in acidosis not related to diabetes.

In old age, when the organs have undergone degeneration from senility, so that there is loss of vitality and functional power, there can be no doubt of the very great importance of alcohol. Used judiciously and with the same care which is exercised in the prescription of other drugs, alcohol often enables an aged person to live on, not only with greater functional power, but with comparative satisfaction. Thus the patient is spared misery of mind and body, and the moral atmosphere of the home is improved. Careful and elaborate studies in nutrition may guide us to accomplish a great deal without the assistance of alcohol, but a satisfactory result may be more easily obtained by having recourse to it, and at times the benefit which follows its regulated administration can be attained by no other means.

In Typhus and Typhoid Fever (Collapse and Convalescence).—In a recent interview published in the *New York Times* (Feb. 20, 1921), Dr. Stephen Smith describes his experiences as an intern working under Alonzo Clark, in the successful treatment of typhus fever by the very liberal employment of alcohol, especially brandy. The success attained through this treatment according to Stephen Smith was extraordinary, and no other measure could compare with it. No one is likely to doubt the wisdom which Alonzo Clark showed in therapeutics, and every one acknowledges the perspicacity of Stephen Smith. Personally I know nothing of the treatment of typhus fever, but there is in this contribution the awakening of a forgotten truth that should be welcomed at this time. As to the value of alcohol in the routine treatment of typhoid, I am in doubt. Having lived through the time when it was generally employed and through a later period when it was excluded, I am unable to come to a definite opinion regarding the question. However, in stages of collapse and in the period of convalescence, alcohol is undoubtedly of value. This observation applies to a wider field than typhoid fever.

In Influenza Pneumonia, in certain phases of other types of pneumonia, alcohol in my judgment is of great value.

Infections.—In grave depression accompanying erysipelas, diphtheria, cholera, cholera nostras, dysentery, and other infections, alcohol may be regarded as of very real value as a substitute for food and as a definite stimulant. Of course it is of alcohol as a temporary remedy, thoughtfully administered, that I speak; when used to excess and habitually it undoubtedly predisposes to infection, through lowering of immunity.

In Chronic Diarrhea, where there is hyperperistalsis, such as occurs in achylia gastrica, amyloid infiltration, tubercular enteritis, in some types of dysentery and in various other local infections, a properly selected alcoholic preparation not merely gives comfort to the patient, but at times is positively a life-saving agent for which there is no satisfactory substitute.

In Diseases of the Circulatory Apparatus alcohol in moderate doses dilates the blood vessels, especially the superficial ones, and according to the U. S. Dispensatory (20th Edition) "increases the amplitude of cardiac action." With these established facts in mind it is understandable why alcohol has become the familiar companion of the victim of angina pectoris. In cardiac insufficiency, especially when the capillary area is narrowed, alcohol is of great value. Here it should be employed in rather frequent small doses, so that it can be completely oxidized and so that its action upon the capillary area may be utilized.

In Nervous and Mental Diseases alcohol, although formerly widely employed with and without professional sanction, has come to be used most guardedly. The objections to its use are evident, and yet there are instances in which it is of very great value. In the depressive psychoses, psychasthenia, and in exceptional cases of neurasthenia, alcohol is at times of value. Its well known predilection for nerve tissue leads the observant physician to be wary of its effects. Many individuals have a remarkable susceptibility to the action of the drug. When used but moderately by such persons there is set up nerve irritability or even polyneuritis.

In Exposure to Cold alcohol acts quickly to restore the circulation and to restore vitality, especially when the subject is placed in a warm room. On the other hand, it diminishes resistance to cold, and when taken before or during exposure to a low temperature, it blunts consciousness, impedes physiological reaction, leads to internal congestion, invites infection, and is generally mischievous.

In Convalescence alcohol preferably should be given in the form of a suitable wine, and its administration carefully guarded by the physician to avoid the well known habit-forming tendency of the drug, especially when the patient belongs to the type of which inebriates are made. Long before the patient is dismissed alcohol should be discontinued and replaced by scientific feeding and psychotherapy.

Alcohol should not be given in quantity greater than that which the organization can readily oxidize. The physician must act as the censor and educator when prescribing the drug, somewhat as with opium or hypnotics. Needless to say, the popular use of alcohol as a preventive and remedy for nearly all illnesses and in case of injury should be most strongly condemned. The harm from the thoughtless employment of this agent has led to its opprobrium.

Finally, it is held that alcohol is an important, sometimes indispensable remedy, that it should be included among the drugs in the Pharmacopeia, that it should be prescribed with discrimination and with a full sense of responsibility, without prejudice, and with careful record of results. The present legal restrictions to the therapeutic employment of alcohol place upon physicians an unnecessary burden and add perplexity to our efforts in relieving human suffering.

436 FRANKLIN STREET.

THE EFFECT OF ALCOHOL ON THE HEART AND BLOOD VESSELS.*

BY LOUIS FAUGERES BISHOP, A.M., M.D., Sc.D., F.A.C.P.,

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE; CONSULTANT IN HEART AND BLOOD VESSEL DISEASES, LINCOLN HOSPITAL; PRESIDENT, GOOD SAMARITAN DISPENSARY.

THE clinical relation of alcohol to the heart is not at all a close one. It cannot be said that alcohol has any direct or immediate effect in producing heart disease. Indeed, alcohol presents a social problem far more than one pertaining to health. Just as the law which compels school children to gaze upon diagrams of stomachs turned purple by alcohol is ridiculous, so it is absurd to attempt to build up a case against alcohol on the basis of the production of organic heart disease.

It needs no argument to procure a conviction of the moral, economic, and mental deterioration which results from the abuse of alcohol, but no one has yet been able to prove that alcohol, divorced from the usual unhygienic accompaniments of the abuse of alcohol, has ever led to organic heart disease. That it results in arteriosclerosis has been disproved by the dissection of many drunkards, dead of pneumonia or other infectious disease.

The great fundamental cause of premature arteriosclerosis in the overworked business man is undoubtedly often founded on the reflex action of worry upon metabolism, and it is more than likely that the moderate use of alcohol at the proper time of day and in the proper quantity, removing as it does this nervous and mental tension and abolishing worry for the time being, may be indeed a preventive of arteriosclerosis.

No one will maintain that alcohol can result in organic valvular disease. As to myocardial changes observed in excessive beer drinkers, it may be said that this has to do in all probability much more with the excessive intake of fluid than with the actual alcoholic content of the beer.

To quote some authorities:

1. One authority says: The extremists, who find no good whatever in alcohol, hold that it is a fallacy to apply the term "stimulant" thereto; that alcohol is a paralyzant from first to last; that its apparent cardiac stimulation is in reality the result of its narcotism of cardiac inhibition; and that every special sense is blunted by even small doses of this poison. They calmly ignore the fact that their premises apply to every stimulant in its special field of action as well as to alcohol in its sphere, and forget that their conclusion (that alcohol has no place in medicine except as a poison) applies by the same reasoning to every other stimulant. Hence, to be consistent, they should advocate the banishment of all stimulant drugs from the materia medica.

2. Another says: In heart disease very little alcohol, either as wine, or as brandy or whiskey, may be allowed to persons accustomed to its use. Beer is less advisable, since it carries with it large quantities of liquid and often disturbs the digestion as well, whereas, wine, whiskey, or brandy in small quantities improves it. Against this is balanced the deleterious effect of alcohol upon the heart muscle. Large quantities tend to produce fatty degeneration of the latter. Whether small quantities have any such effect in the individual case is uncertain, but it must be borne in mind that the injured organ is much more susceptible to deleterious influences than is the healthy organ. It is a safe rule that, in persons not already addicted to its use, brandy or whiskey be given only in doses which serve as carminatives, and not in doses intended for stimulation. Even the psychic effect may often be secured as well by small doses as by large ones. One point in favor of alcohol in man as against animal experimentation lies in the fact that in such persons it greatly increases the sense of well being and removes psychic depression and worry. The latter may be especially straining upon the heart, and hence every effort should be made to ward it off, especially during certain crises; but it should be borne in mind that the patient may easily become dependent upon the drink to arouse his spirits, and in this state more harm than good is done. The greatest judgment should be used in the administration of alcohol even in small quantities, and it should even then be reserved for crises when the stimulation of every fiber is all-important. On the other hand, alcohol should never be withdrawn suddenly from persons addicted to its use, since this procedure often precipitates an attack of delirium tremens, but moderate doses (whiskey 15 c.c. or $\frac{1}{2}$ oz. every four hours) should be given.

3. Another says: Palpitation and the other symptoms of "cardioneurotic" (pseudocardiac) weakness also occur in persons who take alcohol in quantities that are just in excess of their tolerance, and the possibility of this cause must be borne in mind. In some individuals, palpitation and irregularity may follow the ingestion of a single glass of wine, without any symptoms of intoxication setting in. That these conditions may continue without the patient's recognizing the cause is a common experience, and a considerable number of cardioneurotic cases result from this unintentional over-indulgence in alcohol. Women and young persons are more sensitive than men. The functional power and endurance of the heart muscle is, moreover, weakened by alcohol; and acute dilatation may set in from comparatively slight exertion. If the use of alcohol is long continued, it may lead to fatty and fibrinous myocardial change, but this in mild cases subsides when the cause is removed.

4. A writer on the heart says: The degree of dam-

*Read at a meeting of the American Therapeutic Society, June 3, 1921. (See page 300.)

age to the cardiovascular system by alcohol is still a matter of dispute. Like other poisons, it affects the cardiovascular structures to a variable extent, so that necropsy reports showing absence of cardiovascular damage in chronic alcoholism are not necessarily evidence of its innocuousness. It is probably true, however, that the importance and frequency of alcohol as a cardiac poison have been overestimated. Alcohol attacks particularly the cardiac musculature; the result is myocardial disease varying from slight fatty degeneration to scar-tissue formation. The arterial system, when attacked, presents various grades of intimal thickening and calcareous deposits, and, in exceptional cases, degeneration of the remaining arterial coats. . . . In animals, alcohol slightly increases cardiac contractility. In human beings, when given in large quantities, it produces a marked fall of blood pressure by its action upon the vasoconstrictor center and upon the heart muscle. Small quantities of alcoholic beverages seem occasionally to augment cardiac contractility in decompensated cardiac disease, but the effect is slight and inconstant, and its value problematical. . . . There are certain factors which require brief comment because of their influence upon blood pressure. Moderate amounts of alcohol do not regularly raise the blood pressure in man. In the experimental animal, large doses produce a fall in blood pressure, due to an effect upon the vasoconstrictors and upon the heart.

5. The latest book on Heart Disorders that has come to my desk says: Alcohol raises for a few moments the systolic pressure, and thus acts as an apparent circulatory stimulant; it cannot, however, be regarded as a true circulatory stimulant, inasmuch as it decreases cardiac efficiency, raises disproportionately the diastolic pressure, and lowers pulse-pressure, according to the exhaustive investigations of Lieb, corroborated by many others. Alcohol is no longer considered a food, for it has been determined that its oxidation (as is that of uric acid, xanthin bodies, leucin, etc.); it is not oxidized for the purpose of being used by, or stored up in the economy, as a food.

I take it that this discussion is not from the point of view of alcohol as used in the community. As a therapeutic measure, the use of alcohol has undoubtedly served a very valuable purpose in the past as a sedative, particularly in fevers of the typhoid type. It is also necessary to prevent the development of withdrawal symptoms in those who have been previously accustomed to the use of alcohol. This use, of course, under prohibition will need to be employed less and less.

I have never found it desirable or necessary to prohibit the moderate use of alcohol in people suffering from heart disease or arteriosclerosis. In this I find myself in agreement with English authorities, and only out of touch with those of the profession who for some reason or other have been led to believe that alcohol was the cause of organic disease.

A very sharp distinction should be made between the use of alcohol and profound alcoholic poisoning, such as is observed in a person who drinks to the point of coma. In the latter case the extreme physiologic effect of alcohol is observed and manifests itself in a condition resembling shock, with a low blood pressure, cold and clammy surface of the body, and profound stupor. Even so, the circulatory organs have not received any particular damage, the brunt of the poison falling upon the nervous system.

The other question that will arise in these times is whether alcohol is necessary and desirable in the treatment of heart and circulatory diseases and the answer is that there are many better remedies to accomplish any desired effect, but alcohol has often proved a convenience in the relief of angina pectoris or physical collapse because it was ordinarily quickly available. Nitroglycerin and aromatic spirit of ammonia can fulfill every requirement and fulfill it better than alcohol, but in former times one could obtain alcohol where the others were not obtainable.

THE EFFECTS OF ALCOHOL UPON THE ENDOCRINES.*

By CHARLES E. de M. SAJOUS, M.D., LL.D., Sc.D.,
PHILADELPHIA, PA.
PROFESSOR OF APPLIED ENDOCRINOLOGY, UNIVERSITY OF PENNSYLVANIA GRADUATE MEDICAL SCHOOL.

No one, perhaps, more keenly than the medical man recognizes the misery, neglect, starvation, brutality, disorder, crime and pathological processes which, directly or indirectly, are attributable to the abuse of alcohol. In our efforts to assist in overcoming so deplorable a state of things, however, we should not overlook the responsibilities incumbent upon us as legitimate arbiters in matters concerning public health, mental and physical. Particularly does this apply to a question upon which depends to-day a decision of great moment to the welfare of the entire nation, that pertaining to the actual meaning of the word "intoxicating" as applied to alcoholic beverages, left undetermined in the 18th Amendment. In fulfilling our mandate in this connection, however, we should avoid an attitude of mind which is bidding fair to annul and degrade for the future any effort in favor of true temperance, the only line of conduct compatible with the rights and best interests of a free people. By this I mean temperance in all things, just as much in carrying out prohibitive laws as in the use of alcohol itself. Briefly, we should avoid all partisanship, and particularly that pernicious trend too often encountered nowadays even among well-meaning people, fanaticism—a form of obsession in which the mind, by becoming the abject slave of its prejudices, loses all sense of proportion and justice.

Last year, in the Presidential Address before this Society, I submitted evidence to the effect that it was through the endocrines that many of our most efficient drugs and other agents produced their beneficial effects and, when used in excess, some of the phenomena we group under the term "toxic effects." This conception of drug action, the foundation of which was first laid in 1903 and 1907 in my work on the "Internal Secretions," applies likewise to alcohol, and elucidates several admittedly obscure points concerning the pharmacology of this agent. To convey at all clearly, however, the bearing of this statement, it is necessary to review succinctly the functions of those endocrines which are known to be influenced by alcohol.

*Read at a meeting of the American Therapeutic Society, June 3, 1921. (See page 300.)

Beginning with the adrenals, it is believed by many that confusion exists concerning the functions of these organs. Thus, while in 1894 Oliver and Schäfer found that adrenal extract raised the blood pressure, other physiologists showed that it lowered it, particularly when small doses were used. Again, Abelous and Langlois having found that the adrenal hormone possessed antitoxic properties, other physiologists failed experimentally to discern any such action. Even Cannon's familiar emergency theory in which emotional stress—fright, excitement, etc.—is adduced as a cause of excessive functional activity, has been held by others to be fallacious.

All these functions are harmonized, however, when interpreted in the light of a fundamental function I found the adrenals to possess, which was that their secretion sustains respiration and metabolism by supplying the hemoglobin with the substance which enables it in the lungs to become converted into oxyhemoglobin. This view, confirmed by others since it was first formulated in 1903, sustains Oliver and Schäfer's observation that the adrenal secretion raised the blood pressure, since the relatively large doses they used increased greatly the oxygenation and metabolism in the muscular tissues of the heart and blood-vessels, and caused them to contract. Even moderate doses may cause a rise of blood pressure by acting directly upon the first tissues affected by the adrenal principle, the non-striated fibers of the arterioles. These terminal arteries, by contracting, then increase the vascular tension behind them and raise the blood pressure. The apparently destructive observation of Moore and Purinton that minute doses of adrenalin cause dilatation of the arteries also finds its normal explanation, for such doses first contract the vasa vasorum, owing to their minute caliber. These diminutive vessels, supplying as they do, arterial blood to the muscular coat of the larger vessels, cause, when contracted, dilatation of the latter, thus lowering the general vascular tension and the blood pressure. The antitoxic theory of Abelous and Langlois is also readily accounted for in this process, since increased oxygenation and metabolism tend normally to enhance defensive efficiency, while subjects in whom, as in Addison's disease, the adrenals are the seat of organic lesions, are known to be very vulnerable to infection. Finally, Cannon's emergency theory also becomes a normal feature of increased oxygenation and metabolism since the needs of efficient defense require the increased adrenal activity observed by this physiologist.

Turning now to the physiological effects of alcohol, Sollmann[1] writes, referring to its action in moderate doses, typical of stimulation*: "There is an increase in the rate of the *respiration* and of the *heart;* the *blood pressure* rises." He states, moreover, that "stimulant" doses of alcohol also increase markedly "the rate and depth of the respirations" and that "the amount of respired air may be doubled." All these phenomena are typical of increased adrenal function. They are produced, moreover, not only by small doses of alcohol but are also sustained for a time by the prolonged use of alcohol. Does alcohol, however, stimulate the adrenals directly? This was shown by the researches of Bernard and Bigart,[2] who found that slight intoxication increased their functional activity; Aubertin also found in experiments on animals that even chronic alcoholic intoxication caused hyperactivity of the adrenals, with marked hyperplasia. In one of two cases of marked chronic alcoholism studied by Schmiergeld,[4] the adrenals showed changes in the spongiocytes of the glomerular layer which likewise indicated hyperactivity. That these phenomena are brought about by stimulation of the respiratory centers which include that governing the adrenals, is also shown by many experimental facts including the observation of Burge[5] that alcohol greatly increases the catalase of the blood. This catalase is, as my own researches have shown, the adrenal ferment adrenoxidase, thus indirectly sustaining all other observations that alcohol stimulates the adrenals when administered in moderate doses.

Conversely, when large doses are ingested or chronic alcoholism due to the continuous use of large quantities of alcoholic beverages prevails, the functional activity becomes deficient. Thus Bernard and Bigart[2] and also Aubertin found in such cases cellular lesions corresponding with those of hypoadrenia. These effects have likewise been noted by other observers. E. F. Hirsch[6] has also called attention to marked alterations in the cortices of the adrenals in cases of delirium tremens.

On the whole, what observations have been made on the effects of alcohol upon the adrenals show that when employed in therapeutic doses as a stimulant, or used daily in moderation, it promotes the functional activity of the adrenals and therefore general oxygenation and metabolism. This fully supports the observations of Sollmann[1] who states (p. 554), after reviewing the pharmacological domain on the subject, that "*it may be considered as probable—some authorities to the contrary notwithstanding—that a certain amount of alcohol (variable in individual cases) may be taken daily without any demonstrable permanently injurious effect.*" Conversely, it is equally certain that what has very properly been described popularly as "intoxication" and chronic alcoholism tends to cause pathological lesions in the adrenals which may compromise temporarily or permanently, their functional efficiency.

Other factors bearing upon the relationship between alcohol oxidation and the adrenals will be considered presently.

Turning to the thyroid, the fact that this organ is also concerned with metabolism needs only to be recalled. Kendall,[7] who isolated thyroxin, its most active principle, states in this connection: "The changes occurring in a patient with thyroid deficiency, or in experimental animals by the administration of thyroid are so great that practically every cell within the animal organism is changed. The effects are felt throughout the nervous system and the circulatory system, the rate of metabolism is enormously increased and even the skin and hair show revolutionary changes." Moreover, we also find the thyroid concerned with defensive functions. While Victor Horsley in 1892 found that the rôle of the thyroid in catabolism included the breaking down of toxic waste products, my own labors published in 1903-1907 showed that the thyroparathyroid hormone took part in our defensive functions against infections and exogenous pathogenic

agents, the hormone constituting what Wright and Douglas have since termed "opsonin." This has been repeatedly confirmed in Europe. McCarrison,[8] who has himself contributed much to our knowledge in this connection, states in a review beginning with my labors in 1902: "The fact that the antitoxic and bactericidal resources of the body are largely dependent on the functional perfection of the thyroparathyroid mechanism is, I believe, as clearly established as is the influence of this mechanism on metabolism."

What is the influence of alcohol upon the thyroid? The literature of the subject virtually repeats, in respect to this organ, the statements made concerning the adrenals. As stated by Lorand, small doses of alcohol, particularly in weak solution, do not injure this gland, while stimulating it. In a personal practice covering over forty years, twenty of which have been devoted entirely to endocrinology, I have never seen a case in which, even under the influence of moderate daily use of alcohol, the thyroid showed, during life, at least, any sign of functional deficiency. Conversely, the fact that it is stimulated is emphasized by the observations of several investigators to be mentioned later, showing that therapeutic on non-toxic doses increased the defensive efficiency of the body against disease.

As soon, however, as the line of demarcation between the moderate therapeutic or stimulating dose —which, of course, varies greatly in different individuals—is passed and toxic doses are ingested habitually, the whole picture changes. As emphasized by Hertoghe,[9] de Quervain,[10] Sarbach,[11] and Petroff,[12] degenerative lesions, in which sclerosis is a prominent feature, are produced, with all their evil consequences upon the health of the drunkard, including his own vulnerability to disease and what is worse, upon his offspring. Schmiergeld,[4] in describing the histological lesions found in the thyroids of two confirmed drunkards, which showed marked sclerosis, large bands of connective tissue subdividing the organ into many lobules, etc., states that we cannot attribute the changes strictly to alcohol since they may also be caused by tabes, epilepsy, syphilis, etc. The fact remains, however, that alcoholism may be included among the disorders which cause sclerosis of the endocrines in general. Schmiergeld also found sclerosis in the pituitary of his two cases. This is well illustrated in a photophotograph of the pituitary of a confirmed drunkard shown opposite page 1332 in my work on the Internal Secretions.

The morbid effects of chronic alcoholism upon progeny, so well established by a multitude of recorded facts, has also been placed on a solid footing by the labors of Bourneville, Robinovitch, Bernard, Vincent, LeClerc[13] and others, cretinism being the main disorder observed in the offspring. As this endocrinopathy is the most advanced stage of hypothyroidism, it is probable, as my own observations have tended to show, that a far greater proportion of cases of feeblemindedness and backwardness in children than 5 per cent. (which is the proportion of true cretinism among such cases), may be traced to chronic alcoholism in one or both parents. As to its effects upon progeny through the gonads, Simmonds,[14] Kyrle and Schopper,[15] Arlitt and Wells,[16] and others found that alcoholism, also the injection of alcohol in animals, caused practically always changes in the testes, resulting mainly in alterations in spermatogenesis. This appears to be the main effect produced, changes in the ovaries being slight or nil, although sclerotic changes are occasionally found. This analysis of the effects of alcohol upon the endocrines, which effects correspond with those upon other organs, demonstrates also that alcohol in keeping with other powerful tonics, strychnine for instance, stimulates functional activity when administered in therapeutic or moderate doses, and that it becomes an active, destructive toxic when taken in large doses.

Besides the stimulating action of alcohol on the endocrines, however, another factor must be taken into account, to wit, the familiar fact that alcohol is oxidized in the blood and tissues. Now, both the adrenal and thyroid hormones, we have seen, influence powerfully both oxidation and metabolism. How does the oxidation of alcohol square with these glandular functions?

An important therapeutic resource asserts itself in the use of small doses in this connection, while, conversely, large doses find therein an additional power for harm. In the case of small doses, oxidation of the alcohol supplies heat energy to all tissues which is *added* to that produced by its stimulating action upon the adrenals, causing them to unite their efficiency. This parallelism shows itself when they are compared. Thus, Sollmann[1] describes as "stimulant effects" after taking moderate doses of alcohol, an increase of the rate and depth of respiration, the increase in respired air being sometimes doubled, with increase of the systolic blood pressure, particularly where this is depressed, and increase of heart action." In Sollmann's own words, "The amplitude and force of the pulse; the mass movement of the blood; the output of the heart and the efficiency of the circulation in general, will be improved. The effects are not very great and not altogether constant in *normal* individuals, but they suffice to produce decided therapeutic effects especially in conditions of exhaustion."

This corresponds precisely with the action of adrenalin. Its effects are inconstant and often *nil* in the *normal* individual, but we know that it is also in exhaustion when the vascular tension and the blood pressure is low, particularly at the close of acute infections, that it produces its best effects. Alcohol, through its own property of becoming oxidized, and its stimulating action on the adrenals, which itself promotes oxidation, thus combines to form a double source of heat energy and of metabolic activity, culminating in powerful general stimulation towards normal efficiency.

As soon, however, as the therapeutic dose, say 15 to 20 c.c. well diluted, is exceeded, the toxic phase of alcohol begins. This is due to the fact that while a small dose takes up but a small proportion of the body's asset in oxygen, which is readily replaced by an increased intake of this gas, a large dose takes up a greater quantity, more than can be replaced and finally becomes oxidized in part at the expense of the tissue cells including those of the endocrines. Hence, after a period of excitement, the increasing loss of control over the limbs, and when the dose has been sufficient, the total loss of muscular power, etc., which constitutes the "dead drunk."

Another important distinction between therapeutic and toxic doses of alcohol asserts itself when it is recalled that both the adrenals and the thyroid take an active part in the defensive processes against infection. Since, as we have seen, alcohol in therapeutic doses stimulates these organs, it should in such doses increase defensive activity, while, conversely, large doses which depress these glands should lower defensive activity. This is precisely what independent observation has demonstrated. As far back as 1903, Hobart A. Hare[17] found as the result of a comprehensive study, that alcohol combatted infections by increasing the bacteriolytic power of the blood when administered in ordinary medicinal doses. This corresponds with the observations of Müller,[18] Wirgin,[19] Parkinson,[20] and others. Parkinson's experiments showed, moreover, that while small quantities of alcohol temporarily increased the production of antibodies, large doses caused the opsonic index to fall. If these large doses were persisted in, the opsonic index remained low, permanently indicating failure of the defensive mechanism. The protective value of small doses of alcohol in free dilution was also illustrated repeatedly during the world war. Conversely, the predisposition of the drunkard to infections and the unfavorable prognosis chronic alcoholism entails in these diseases are too well known to require emphasis.

Finally, as is well known, the benefits derived from the moderate use of alcohol manifest themselves mainly in the direction of recuperation after great fatigue, during convalescence from debilitating diseases, or in the debility due to old age. This also coincides with the main indications for adrenal preparations—a suggestive fact in view of the stimulating action of therapeutic doses of alcohol upon the adrenals previously mentioned. During the war it was found by Josué,[21] Satre and Gros,[22] and others, that overstrain in troops, with symptoms of cholera (Asiatic cholera having been shown by myself in 1903 to correspond symptomatically with complete adrenal failure, a fact also confirmed during the war by the remarkable effects of adrenal injections) was promptly arrested by the use of adrenalin. While alcohol has long been our sheet anchor in the threatening heart failure often witnessed at the close of acute infections, we now know that intramuscular injections of adrenalin in 8-minim doses of the 1-1000 solution has the same effect while acting more promptly. In the aged, atrophy of the adrenals is now fully recognized pathologically and clinically as an underlying cause of their weak heart and circulation. Ample experience has shown that the moderate use of alcohol is of great value in the elderly—doubtless due to its stimulating action on the adrenals. The workingman after a hard day's labor experiences great relief and a sense of well-being from a couple of glasses of beer or wine which, by stimulating his endocrines, his systemic oxidations, and his circulation, aid in the catabolism of fatigue wastes. Known as these wastes are to breed bad temper and irritability, the temperate use of such stimulation, by creating a sensation of comfort and well-being, replaces these elements of family trouble by geniality and cheerfulness, which make for good fellowship. Again, does science confirm biblical text:

> He causeth the grass to grow for the cattle, and herb for the service of man that he may bring forth food out of the earth, and *wine that maketh glad the heart of man.* Psalm civ, 14, 15.

As to the dilutions of alcohol which prove harmless even in large quantities, the consensus of opinion among pharmacologists is well summarized by Sollmann[1] who, after reviewing its effects upon the mental attitude, the circulation, the digestion, etc., states that "alcohol should be taken well diluted as light wines or beers." The more recent investigations only serve to confirm the teachings of many decades. H. M. Vernon,[23] for instance, in a comprehensive study of the question for the British Central Control Board, in which various dilutions varying from 5 to 40 per cent. solutions were used with impairment of neuromuscular coordination as index, speaks in the same direction. Higher dilutions than 5 per cent. were all found harmful, but the effects of alcohol taken in considerable dilution were found to be much slighter than anticipated. Indeed, he remarks in this connection: "Practically speaking, beer containing 3 per cent. by volume of alcohol or 5.25 per cent. proof spirit is a non-intoxicating liquid."

As to light wines, white or red, the sobriety of districts in France, Italy and Spain in particular, where such are used as usual beverage, speaks in the same direction. This is well illustrated among our own laborers, the best, most orderly and most industrious of which are the wine drinking Italians, as all road contractors will testify. Again, claret is a prophylactic against a class of deficiency diseases now receiving much attention. Suggestive in this connection is the fact, recalled by Bouchardat that claret prevented the development of scurvy aboard a French war-vessel, one of two detained in the South Seas, while the disease developed aboard the other, a British vessel, upon which the usual ration of rum was used. Prof. Bouchardat ascribes the salvation of the French crew to the inorganic matter and particularly the potassium salts contained in their wine. The proportion of alcohol in natural wines varies from 5 to 15 per cent. but the quantity consumed at one time, even of the finer vintages, is far below that of beer, because of their tendency in any large amount, to disturb the stomach, owing to the tannates, ethers, and essential oils they contain. Hence the rarity of intoxication due to wine.

Very different, however, are the percentages of alcohol in whiskey, brandy, gin, rum, etc. (44 to 55 per cent.) which percentages are the real source of all the ills attributed to alcohol as a whole and the use of which it should be our aim to discourage.

Conclusions.—All these facts, which could be multiplied almost indefinitely, owing to the vast amount of literature available upon the pharmacology of alcohol, suggest the following deductions:—

1. Alcohol either stimulates, depresses, or causes organic lesions in the endocrines, according to the quantity consumed, and, as such, in keeping with other therapeutic agents, proves beneficial in small or moderate doses, but harmful in large doses, *i.e.* when such exceed, either singly, or cumulatively, certain limits.

2. Pharmacology: Alcohol increases general metabolism: (1) by becoming itself oxidized and thus

increasing the heat energy liberated in the blood and tissues; (2) by stimulating the adrenals, which govern the intake of oxygen, and sustain anabolism, and (3) by stimulating the thyroid which sustains catabolism.

3. In stimulating but non-toxic doses alcohol increases the functional activity of the endocrines. This action, through the adrenals and thyroid especially, increases the cardiovascular tone, respiratory activity, the rate of metabolism, and the efficiency of the defensive functions.

4. In toxic doses, the excess of alcohol taken becomes oxidized at the expense of the oxygen in the blood. The tissues, including the endocrines, being inadequately supplied with oxygen, their metabolic rate is slowed, the cardiovascular tone is lowered, and the defensive efficiency of the body is reduced, giving rise in marked cases to the symptomatology of acute alcoholism.

5. When the use of toxic doses of alcohol is prolonged, or becomes habitual, the excessive heat energy developed in the tissues by the oxidation of the alcohol increases sufficiently the proteolytic activity of the tissue enzymes to cause autolysis in various highly differentiated tissues including the endocrines, causing therein focal lesions which lead to sclerosis.

6. Therapeutics: Small doses in free dilution are indicated because of their stimulating action upon the adrenals. These organs, by increasing the oxygen intake, add to the heat energy liberated by the oxidation of the alcohol itself, a potent agency for the prompt acceleration of cellular metabolism which entails a correspondingly rapid resumption of depressed vital functions. Hence, the familiar fact that alcohol is indicated in such conditions as circulatory failure including that of acute infections, fainting, shock (all of which conditions, when threatening, may be further counteracted by also giving intramuscular injections of adrenalin), convalescence, senile debility, overstrain, fatigue, etc.

7. General Uses: Beverages containing 3 per cent. by volume of alcohol such as light beers, cider, etc., are nonintoxicating because of the necessity of ingesting too great a volume of fluid to cause any degree of intoxication. Light wines, white or red, containing 5 per cent. by volume of alcohol are likewise nonintoxicating partly for the same reason, but particularly because any large quantity of wine tends to produce gastric discomfort owing to the tannates, ethers, aldehydes, essential oils, etc., they contain, thus automatically precluding intoxication.

8. The cause of true temperance would be better subserved and a large majority of the antagonists of prohibition would lend it their support for public good, if in its details, the law enforcing it were compatible with the teachings of science and with the needs of the workingman and others in whom fatigue, debility, physical and mental depression, justify the use of nonintoxicating beverages such as light beers, cider, etc., containing not more than 3 per cent. of alcohol by volume, or light wines containing not more than 5 per cent. by volume. The Volstead Act which imposes the rule that one-half of one per cent. of alcohol is intoxicating within the intent of the Prohibition Amendment is not sustained by a single scientific fact, and, as all wrongs invariably do, is steadily defeating its object.

ALCOHOL IN SURGERY.*

BY ROBERT T. MORRIS, M.D.,

NEW YORK.

ALCOHOL possesses a sort of universality which has led it at various times into several fields of surgery. On the whole, we may say there appears to be no place in which it holds a superior position to other agents which may be employed for the purposes for which alcohol is employed.

In advance of the days of ether anesthesia, patients about to undergo surgical operation during the days of the heroic era in surgery were sometimes put profoundly under the influence of alcohol —a resource which is said to be still employed among some of the native tribes in Africa and in remote districts elsewhere, where anesthetics are not available. Alcohol was at one time used in combination with chloroform and ether in what was known as the A. C. E. mixture, which was supposed to lessen the refrigerating action of sulphuric ether and chloroform and at the same time add a certain stimulating influence which would overcome the depressing influence of chloroform. The A. C. E. mixture has, however, now passed out of use for the most part.

In some of the neuralgias alcohol has been used for injection purposes, particularly in trifacial neuralgia, sciatica, and neuralgia of the superior laryngeal nerve occurring in tuberculous laryngitis. Osmic acid, however, in weak solution seems to be more effective and with longer duration of influence than alcohol. Both of these substances are injected directly into the nerve pref-

* Read at a meeting of the American Therapeutic Society, June 3, 1921. (See page 300.)

erably, although sometimes alcohol in the nerve sheath will suffice to halt the severe neuralgic pain. In all probability this action is secondary to a coagulation of albuminous elements in the nerve structure, and the neuralgia is prone to return after a restoration of the nerve elements to normal condition, which naturally occurs spontaneously.

Alcohol as an evaporating lotion diluted with water is a valuable agent for cooling purposes in cases of contusion. Gauze moistened with an alcohol solution and gently fanned produces a very grateful refrigerating effect.

Alcohol has a place in the preparation of surgical instruments. In emergency, other means not being available, certain instruments may be sterilized by "flaming" by means of alcohol. In some operating rooms it is the custom also to boil sharp-edged instruments for one to three minutes only and then immerse them in 70 per cent. alcohol. When knives are sterilized by immersion in pure carbolic acid, they are immersed in alcohol before being used. As a general disinfectant of instruments, however, alcohol at ordinary temperatures cannot be considered to be useful. Various experiments on the part of a number of observers have shown that alcohol is not really a germicide, but it may act as an antiseptic with inhibitory action upon the growth of bacteria. There seems to be evidence that certain bacteria resist the action of 95 per cent. alcohol, that they are not affected by a 50 per cent. solution, and yet 70 per cent. seems to penetrate the bacterial tissue and act as an agent inhibiting bacterial growth. Some species of bacteria, the colon bacillus, for example, are injured more by a very strong solution than by the weaker ones, this matter of response to alcohol varying with different kinds of bacteria.

Alcohol is used extensively as one of the substances for hand preparation and for preparation of the skin of the patient in advance of operation. Its action here, however, belongs to nothing more than that of a general solvent for removing sebaceous material and other materials which hold bacteria upon the surface of the skin. Scrubbing with green soap presumably does more than is done with alcohol in this way, and it has the special advantage of not hardening the epithelium of the hands of the surgeon. Alcohol, being hygroscopic, abstracts a certain amount of water from the superficial epithelium so that a surgeon who employs it several times in the course of a day would lose a certain degree of delicacy of touch that goes with soft skin.

Alcohol in weaker solutions, not stronger than 25 per cent., appears to have been beneficial at the hands of a number of gynecologists for flushing purposes in cases of septic endometritis in connection with a drainage device. The empirical results recorded do not take into account the fact that alcohol is not a germicide, and we apparently have some local stimulating effect upon the normal tissue cells leading them to resist bacterial invasion. The unknown factor may relate to the astringent action of alcohol.

Alcohol has been employed as a preservative for catgut, but it exerts germicidal influence only at boiling temperature and under pressure.

Alcohol as a stimulant after surgical operation, for the purpose of overcoming the effects of shock and for stimulating flagging energies into activity, appears to have a place of considerable importance at times, although a good deal of judgment on the part of the surgeon is required in order to avoid injurious action. Continuous vomiting after surgical operation is sometimes quieted promptly by small doses of champagne, and patients who are making slow recovery from the shock of operation occasionally make prompt response for the better when alcohol is given in the form of good wine or spirits.

In conclusion we may state that alcohol as an antiseptic and anesthetic in surgery has negligible value, and as a stimulant it has limited application.

616 Madison Avenue.

Medicolegal Notes.

Expert's Opinion Must Be Based on Facts, and Does Not Prove the Existence of the Facts.—In an action on an accident insurance policy against death by external, violent, and accidental means, and excepting death or loss from inhaling gas or asphyxiation, three witnesses testified that they saw a reddish spot on the deceased's temple a short time after his death, and a physician, in response to a hypothetical question, testified that in his opinion the death was attributable to the external signs of violence over the temple. It was held that this evidence was not sufficient to authorize or support a finding by the jury that the deceased came to his death by violent, external, or accidental means, and not by asphyxiation from automobile fumes, as stated in the death certificate and proofs of loss. The court said: "The opinion of the physician as to the cause of death is invoked to supply the substantive facts necessary to support his conclusion. This cannot be done. It is the function of opinion evidence to assist the jury in arriving at a correct conclusion upon a given state of facts. To endow opinion evidence with probative value it must be based on facts proven or assumed, sufficient to enable the expert to form an intelligent opinion. The opinion must be an intelligent and reasonable conclusion, based on a given state of facts, and be such as reason and experience have shown to be a probable resulting consequence of the facts proved. The basis of the conclusion cannot be deduced or inferred from the conclusion. In other words, the opinion of the expert does not constitute proof of the existence of the facts necessary to support the opinion."—Dreher v. Order of United Commercial Trav. of America, Wisconsin Supreme Court, 180 N. W. 815.

Where there is a dispute about the existence of the facts stated in a hypothetical question, it is the exclusive province of the jury to determine whether such facts do exist. The truth or existence of each and every fact included in the hypothetical question is assumed. The opinions of the experts are built upon the assumption, and if this foundation falls the superstructure goes with it. Therefore, if the jury finds that any fact stated in the hypothetical question is untrue, does not exist, the jury must then disregard the opinion of the experts. But, on the other hand, if the jury finds that all the data stated in the hypothetical question exist, are true, the jury must consider the opinion of the experts in connection with all the other evidence in the case.—Kelly v. State, Arkansas Supreme Court, 226 S. W. 137.

Consideration of Medical Opinion Without Opportunity to Cross-Examine Is Error.—The Appellate Division holds that the consideration by the State Industrial Commission in a workmen's compensation proceeding of a written opinion of a physician as to the cause of death after the hearings were closed, so that no opportunity for cross-examination of the writer of the opinion was offered, was error, necessitating reversal of the award.—Jack v. Morrow Mfg. Co., 194 App. Div. 588.

THE CONNECTIVE TISSUE FRAME-WORK OF UNSTRIATED MUSCLE.

WHEN a good tissue for study is selected, such as the esophagus of the turtle in which the special interstitial connective tissue is very developed, it would appear that this tissue is essentially composed of precollagenous amorphous connective substance in which only a few fine elastic fibers are found. The amorphous substance composing the major part of this interstitial tissue is finely alveolar, the alveoli communicating more or less among themselves. The occasional presence of nuclei which are directly included or separated from it by a thin layer of endoplasm would seem to indicate that this represents a protoplasmic alveolar rete which has undergone a transformation in exoplasm in most or all of its extent. Garnier has reached different conclusions purely because his staining methods were imperfect. For this reason the trabeculæ of the rete were ill-defined in his sections and he therefore regarded them as fibers while in reality they are true thin laminæ marking off the alveoli. This alveolar rete is not a new discovery but it has been made perfectly evident by Lemoine. On the other hand, Lemoine has shown that at the limits of the submucosa it gradually continues with the fibrillary connective tissue. Its amorphous stroma is slowly invaded by true fibers which deform it more or less completely. To the very delicate framework formed by them another and grosser framework in which fibers predominate, becomes substituted; on the other hand, in the general connective tissue of many invertebrate animals, a similar fine alveolar rete is present, but with still more incomplete septa. By proper staining methods as described by Lemoine, Schneider, and others, it will be seen that the whole of the neighboring septa of the alveoli nearest to the muscle fiber are in contact with it so as to give it a continuous sheath.

Lemoine's researches concord with those carried out by Schäfer on other organs possessing abundant interstitial tissue, since they both reach about the same conclusions. In organs with little interstitial tissue development—arteries and veins of mammiferous animals—Lemoine found the same arrangement, only here, between two neighboring fibers usually one or two rows of alveoli existed, a condition frequently met with in the turtle; these alveoli were very small and often so compressed as to be flattened out. It is probable that either by osmosis or perhaps by direct communications a current of interstitial lymph circulates through the alveoli and bathes the muscle fiber. All these descriptions show the importance of the amorphous connective substance because it alone may form a supporting interstitial framework.

The study of the adult aorta shows the presence of elastic laminæ included in an amorphous lamina of the same nature and further emphasizes this importance. Histogenesis explains how the connective lamina at first alone exists and how the elastic substance appears within it later on. The amorphous connective lamina is itself due to a thickening and regularization of the amorphous substance between each stratum of unstriated fibers in which they are embedded and thus forms a sheath for each. On account of the absence of connective cells, strictly speaking, between the unstriated muscle fibers of the aorta undergoing differentiation, it would seem that this amorphous substance represents here, not as elsewhere the exoplasm of the connective tissue cells, but the exoplasm of young unstriated muscle fiber. Thus the cells of the mesenchyma in the wall of the aorta may evolve in two directions, some becoming connective tissue cells, others becoming unstriated muscle; but it would appear that in both the young and less differentiated state the most superficial strata of the protoplasmic bodies can become differentiated into a precollagenous exoplasm, that is to say amorphous connective substance.

The conclusions that may be deduced from recent studies are that no intercellular cement is present between unstriated muscle fibers, nor are there any intercellular bridges. The fibers are plunged in an amorphous connective substance, very finely alveolar, which forms a sheath around each one. In organs with abundant interstitial tissue there may be several rows of alveoli, otherwise there is usually but a single row between each fiber. The alveoli become still more numerous and are not arranged in rows between two adjacent fasciculi. True connective tissue fibers and fine elastic fibers may be found here and there within the lamellar septa of the alveolar rete, but they are usually very sparse, and are best developed in the veins. The elastic laminæ of the large arteries develop in the midst of an amorphous connective lamina and always remain included within it. The amorphous connective substance can probably be derived directly from the unstriated muscle cells in the form of exoplasm, as it is likewise derived from the connective tissue cells.

ABNORMAL SENSITIVENESS TO MUSHROOMS.

THIS behavior is naturally quite distinct from the mushroom poisoning due to the presence of toxic alkaloids, and has been noted so rarely in literature that Azoulay does not seem sure that his observa-

tions are not unique. His article on "sensitiveness to edible fungi" appears in the *Bulletin Médical* for May 11-14, 1921, xxxv, 20. However rare in literature, the condition itself cannot be rare, as shown by answers to questions put to various people. The first patient whose case is described was a woman of 35 of excellent digestion and free from any irregularity of the bowels. At the age of 22 she had eaten of the mushroom known as the *Psalliotes* in company with her family, none of whom complained afterward. There were no symptoms during the digestive period, but later she suffered from an intense diarrhea. Ever after when she essayed to eat any kind of mushroom, wild or bedded, she experienced the same symptom. It was only necessary to eat about one cubic centimeter of the fungus to obtain this effect. The duration of the bowel trouble was around 18 hours. Apparently she was not sensitive to any other article of diet, although once she was poisoned by eating tainted meat. Another woman, aged 50, was healthy and of good digestion but somewhat predisposed to attacks of diarrhea from no apparent cause. At the age of 16 or 18 she had partaken of certain kinds of mushrooms with other people, of whom none other was taken ill. On this and subsequent occasions she paid for the indulgence by attacks of diarrhea so severe that she was compelled to abstain from mushrooms for life, as she supposed. At a much later period she ate cultivated mushrooms in Paris and had comparatively little trouble. A third woman aged 65 was made very ill by eating mushrooms and mussels and she was also abnormally sensitive to the action of drugs of all sorts.

While we have stated that this sensitiveness to mushrooms in the absence of alkaloidal poisons in the latter cannot be regarded as cognate with true mushroom poisoning, it must nevertheless be remembered that there is a marked personal equation in the latter, the sensibility of individuals showing much variability. But in the case of the edible mushroom an anaphylaxis is clearly suggested, although in the absence of details this cannot be demonstrated. The author thinks his third case was anaphylactic, but is not sure about the others. He assumes that the first episode was connected with eating mushrooms for the first time and the second as well. This does not appear in the histories. He would agitate the subject by having medical men put interrogatories to people who are exposed much to the consumption of mushrooms. Data of importance are the age, the usual condition of the digestive tract, the first date when mushrooms were eaten, and the reaction, if any; and if none was present on this occasion the date at which the first poisoning occurred, the species eaten, and whether well cooked or not, whether ordinary indigestion was ever experienced, the relative experience with wild and cultivated fungi, the number of crises which followed the indulgence, etc., etc. Other data of special interest concern the possible existence of a family idiosyncrasy and of anaphylaxis or simple poisoning by other familiar dietetic articles.

VASCULAR HYPERTONUS AND HYPERTENSION WITH ARTERIOSCLEROSIS.

Professor Pal writes on this subject in the *Wiener klinische Wochenschrift*, xxxiv, 6. The three conditions, he states, are commonly regarded as almost synonymous with one another, but hypertonus is an active state of the smooth muscle while hypertension refers to the lateral pressure on the vascular wall. Two factors are therefore concerned, one kinetic and the other biological. The tone of the muscle determines or regulates the kinetic function. The muscle tone is a matter of muscle consistency, and the latter has to do with the stratification of the muscle cells. With increased tonicity the artery becomes harder and the difference can be estimated by the touch. Not only quantitative but qualitative alterations are recognizable. Normally arteries are barely palpable, but in hypertonus they are palpable in various degrees. In some cases the hardness is persistent, in others it may abate with time. Since there may be hardened arteries with weakened heart action the phenomenon can have no necessary connection with increase of blood pressure, although in general increased tonus is associated with increased tension. Again high tension over long periods does not necessarily mean an anatomically altered artery. Presumably the muscle elements show some increase in number or size. To realize that long hardened arteries may suddenly become soft one has only to study the vessels on the paralyzed side of a hemiplegic. The arterial tonus is certainly a component of the blood pressure, but one which has been greatly overvalued. The finger is a most fallacious guide in these cases, for the caliber of the artery may vary greatly. A narrow hypertonic artery feels very different from a wide one, yet the former is seen in secondary contracted kidney, while the latter may sometimes be encountered in the arteriosclerotic kidney. Narrow rather than wide is the rule in hypertonic vessels.

To distinguish blood pressure from arterial hypertonus the use of instruments is an aid, but it does not appear that as yet we can measure either alone. The author, however, has contended for the autonomy of an essential hypertonus—primary, of course—of the arteries. This affection is virtually new—a functional arteriosclerosis. Apparently it may accompany polyglobia, but the author refers to an independent form concerning the origin of which we as yet know but little. It is at first without symptoms, latent—but in time a picture develops of enlarged heart with its congestive states, headache, insomnia, irritability, etc.

Our word arteriosclerosis is a rather confused conception. One form counts among the degenerative phenomena and is best called atherosclerosis.

Calcification of the media is something apart from the latter, for it is general, while atherosclerosis is focal. A presclerosis which ends in atherosclerosis does not exist as a universal phenomenon, for there is much arteriosclerosis which does not terminate in the degenerative phenomena. Both of these are seen exceptionally in young and even very young subjects. In the author's primary permanent hypertonus he has not found atheromatous foci in the large vessels. That mechanical factors alone can produce high pressure and sclerosis has been shown classically for the pulmonary artery by Ljungdahl. But if we can clamp off the limb arteries the protracted hardness and even the convoluted arrangement may soon vanish, showing that kinetic factors alone were present. There is apparently a direct connection between cases of functional hardness and calcification; in both the media is affected and the condition is general, not focal. Often, however, the differential diagnosis is impossible.

Tuberculous Salpingitis.

Although there is much evidence in the literature that the frequency of tuberculous salpingitis has been recognized by many of our prominent gynecologists, it seems possible that general practitioners, those who see the patients first, have failed to appreciate how common this affection really is. It is possible that we are doing the physician an injustice, for this opinion must necessarily be based upon impression rather than any statistical evidence. But in any event it seems profitable to call attention to Greenberg's article on the subject in *Johns Hopkins Hospital Reports*, xxi., 2, 1921, and to emphasize anew the important place which tuberculosis of the tubes has come to occupy. Greenberg found that almost 1 per cent. of more than 24,000 patients suffering with gynecological disorders had tuberculous salpingitis and that one in each thirteen pathological tubes examined showed the lesions of tuberculosis. At first sight these figures appear extraordinarily high, but they are in agreement with those obtained by other investigators and there is no good reason to believe that Greenberg's experience differs essentially from that in other large gynecological clinics. A preoperative diagnosis is unusually difficult and there are many instances in which the condition was first recognized on microscopic examination of the excised tubes. With careful physical examination and complete history it may be possible at times to make a tentative diagnosis and in the presence of ascites the diagnosis is relatively simple. Greenberg notes that the majority of the patients showed tenderness in the lower abdomen, menstrual disturbances, pain and leucorrhea, while about one-half or more showed some anemia and loss of weight. In 70 per cent. of the patients masses were found in the fornices. The picture is admittedly not a clear cut one, but the existence of the condition may be suspected much more often if it is always thought of when considering the diagnosis in a gynecological condition. While tuberculous salpingitis is a serious condition, especially when associated with tuberculosis elsewhere in the body, it appears to show some tendency to healing and it is probable that with early recognition and proper care a large percentage of these patients would recover.

The Hemoclastic Crisis.

The expression "hemoclastic crisis," or hemolytic crisis, having recently come into familiar use, Laumonnier gives to the readers of the *Gazette des hôpitaux* for June 22-24, 1920, xciii, 56, some timely information on the subject. He prefixes it with a summary of anaphylaxis and anaphyiactic shock and relates that in 1913 the distinguished clinician Widal made the discovery that in a certain case of alimentary anaphylaxis the shock was preceded by a vasculosanguine crisis comprising the following manifestations: lowered blood pressure, diminished number of white globules with inversion of the normal leucocyte formula, rarefaction of red cells and hematoblasts, modifications of coagulability, shining appearance of the venous blood, etc. This condition lasts several hours and is followed by a reaction in which some of the changes are overcompensated. Since that date innumerable experiments have been made on the hemoclastic crisis, and while much information has been gained the nature of the phenomenon is still obscure. The crisis followed by the shock is elicited by a variety of substances, comprising peptones, proteins, colloidal solutions, sera, etc. In a malarial access the entrance into the blood of the merozoites, which are foreign bodies, produces a hemoclastic crisis followed by shock which is no other than the malarial rigor and febrile attack. Again hemoglobinuria *a frigore* is the expression of a hemoclastic crisis, despite the fact that no foreign substance has gained access to the blood. Instead the cold appears to have denatured some of the protein compounds of the individual which then behave as heterologous substances. Attempts to limit these behaviors to colloidal activities have been unsuccessful, for a certain quantity of hypertonic saline infusion has produced the crisis and subsequent shock. The hemolytic crisis makes it evident that our knowledge of anaphylaxis is in its infancy, and it is also evident that this crisis figures in some way in the great majority of serological phenomena.

News of the Week.

Cholera Spreads in Starving Russia.—A special despatch to the New York *Times*, under date of August 4, states that Moscow authorities have officially admitted that there are 47,779 cases of cholera throughout Russia, and have also tacitly admitted that the number is on the increase. According to Soviet figures, there were in all Russia between January 1 and July 15 of this year 47,779 cases of cholera, of which 24,000 occurred in June. Observers on the Russian border in close touch with conditions believe these figures are below the actual number of cases.

Pellagra Conference Opens in Washington.—The conference called at the suggestion of President Harding to discuss the pellagra situation in the Southern States began on August 4. Those participating included Surgeon General Hugh S. Cum-

ming and other officials of the Public Health Service, health officers of the Southern States, with the exception of Georgia and Texas, and representatives of the American Red Cross and the Department of Agriculture. Mississippi was the only State that presented complete statistics. From January to June last in that State 5,417 cases of pellagra were reported as against 2,763 cases for the corresponding period of 1920, an increase of approximately 100 per cent. Oklahoma admitted that there were within her borders about 500 cases.

The Senate Passes the Willis-Campbell Bill.—The anti-beer supplement to the Volstead law was passed by the U. S. Senate on Monday of this week. The bill forbids physicians to prescribe beer for their patients. The vote passing the bill was 39 to 20. Those who voted against the bill were Senators Ball, Brandegee, Broussard, Cameron, Gerry, Johnson, King, La Follette, Lodge, McLean, Moses, Penrose, Phipps, Ransdell, Shortridge, Stanley, Pomerene, Wadsworth, Warren, and Weller.

Smokers Incorporate to Protect Rights.—The Supreme Court has given approval to the certificate of incorporation of the Smokers' League Against Tobacco Prohibition, Inc. According to the certificate, the objects of the new organization are "to establish and conserve the right of the citizens of the United States of America to use tobacco." The incorporators are all business and professional men of Greater New York.

South Carolina Licenses Physicians.—The State Board of Medical Examiners of South Carolina announced on July 29 that twenty-one doctors, fifty-eight nurses, and one osteopath had successfully passed the examinations conducted by the Board in June and had been licensed to practise their profession.

Medical Society Announces Legislative Program.—The Welfare Committee of the Medical Society of New Jersey announces a legislative campaign for the ensuing year, embodying opposition to every member of the House of Assembly who voted against the medical men's bill which would raise the educational standard of those who would practise healing and setting forth a general line of legislation which the medical profession will seek at the next Legislature. No names of assemblymen to be opposed were given, it being specifically stated that such action was the function of the various county medical societies. An amendment to the workmen's compensation law is also proposed "which will provide for the fair and proper compensation for the physicians and hospitals who are called upon to care for persons injured in industry." Opposition to compulsory health insurance is also voiced.

Increase in Suicides.—The semi-annual report of the Save-a-Life League, submitted by its president, Dr. Harry M. Warren, on August 7, shows that during the first six months of this year there were in New York City 443 suicides, of which 319 were men and 124 women. This is an increase of 102 over the same period for 1920. The report notes that while 225 children ended their lives during the first half of 1920, the number has more than doubled during the first six months of 1921. Many of these children gave school conditions, especially examinations, as the cause of their desire to kill themselves. The report indicates that throughout this country and the civilized world there has been a wave of suicide. During the first half of 1920 there were reported to the league 2,771 suicides in the United States as against 6,509 for the corresponding period of this year. This large increase is attributed to business depression, economic disturbances, and the general abnormal conditions of the war's aftermath.

Physically Strong Children Best Pupils.—The Detroit News reports the results of an investigation of 84,000 school children which shows that the physically robust child is far in advance of the weaker youngster of similar age as regards scholarship. Taking the grade for a child of normal weight and height for his age at 100, it was found that if a child is two and one-half years ahead of his age group in school he is also, as a rule, 10.2 per cent. higher and heavier than the ordinary child of his age. In the same way it was found that a child 9.5 per cent. under weight and height for his age is four years behind in his school work. The difference among the girls was slightly less than among the boys. The report states, however, that there are many factors—nationality, hereditary characteristics, etc.—which in different individuals tend to modify these conclusions.

Trustees Urge Restoration of Polyclinic Hospital.—In the name of the trustees and medical staff of the New York Polyclinic Hospital, Dr. John A. Wyeth protests "against the injustice of the further prolonged occupancy of this property by the Public Health Service of the United States," and appeals "to the State and municipal officers and to every man and woman who believes in the recognition of an honorable obligation to aid in bringing such pressure to bear upon the authorities at Washington that this great hospital—serving one of the most populous districts in the city of New York, in which there is a great shortage of hospital accommodations for the largely increased civil population may be returned to its owners and again used for the benefit of the people." The protest recalls that the hospital was turned over to the Medical Corps of the War Department during the World War and that the War Department transferred it to the United States Public Health Service against the wishes and the written protest of the trustees. It is pointed out that two years have elapsed since the Public Health Service took possession of the property and that it has persistently refused to relinquish its occupancy on the pretext that we were still at war inasmuch as the treaty of peace had not been signed.

Sanitary Code Regulates Noises from Automobiles.—At a meeting of the Board of Health of New York City on July 25 resolutions were adopted amending the Sanitary Code with the object of suppressing unnecessary noises from automobiles and other motor vehicles. The resolutions prohibit loud and explosive noises and require that engines shall be constructed so that the exhaust is made to discharge into a muffler or other device which will prevent loud or explosive noises, and

that no person having the management of an automobile shall allow the exhaust from such an engine to discharge into the open air. The resolutions further require that horns and other devcies for signalling shall be used in a reasonable manner as a danger warning only and shall not be continued for an unnecessary and unreasonable period of time.

Memorial to Dr. Trudeau.—A memorial window erected in the Episcopal Church of St. John in the Wilderness at Paul Smith's, N. Y., by William Rockefeller, in memory of Dr. Edward Livingston Trudeau, was dedicated on August 7. The dedication service was conducted by the Rev. Philemon F. Sturges of Providence. St. John's in the Wilderness was built of logs in 1887, Dr. Trudeau having started the work four years after his first visit to the Adirondacks.

Osteopaths Oppose a Secretary of Health.—The American Osteopathic Association, at its annual meeting held in Cleveland, Ohio, July 27-30, put itself on record as opposed to the Owen bill and Kenyon-Foss bill, claiming that this legislation would create State medicine and give to one school of healing a monopoly. The association is also opposed to the Sheppard-Towner bill.

War Memorial for Post-Graduate Hospital.—The New York Post-Graduate Hospital is having set up a huge bronze memorial tablet in memory of the medical officers, nurses, and enlisted men who formed a unit from that hospital and served in the American Expeditionary Forces in France, and which functioned under the unit name of Base Hospital No. 8, A. E. F., Savenay, Loire-Inférieure, France. Five of its members lost their lives while in the service. A gold star is placed opposite each of these names on the tablet.

Malaria Discovered Among Immigrants.—The New York Health Department has received information that some of the hospitals in the city have found malaria among newly arrived immigrants. This disease is among those certified as reportable, and because such immigrants might serve as a spark to light up a very considerable outbreak of this disease the Health Department urges that physicians should remember that it is their moral and legal duty to report to the department at once each and every case of malaria that comes under their professional notice. The Health Department further reminds physicians that the aid of the laboratory should be sought in all diagnoses of this disease.

Deaths from Narcotics in New York City.—A report submitted to the New York City Health Department from the Chief Medical Examiner of the City of New York for the years 1918-1921 shows that during this period there were 164 deaths from narcotic poisoning, of which 107 were due to morphine, 24 to opium, 27 to heroin, and 6 to cocaine. Of these deaths 65 occurred in 1918, 56 in 1919, and 43 in 1920.

Male Births in Germany During the War.—According to statistics which have just been announced, the average birth ratio in Prussia is 103 boys to each 100 girls, but during the war the ratio was 107 boys to 100 girls. The same phenomenon was reported during the Franco-Prussian War, but the accuracy of the figures was questioned then because of the imperfect methods for gathering statistics.

Gifts for New Broad Street Hospital.—The Downtown Hospital Association, New York, reports that at the end of the first week's campaign for $1,000,000 for the Broad Street Hospital building fund $257,000 has been contributed. An anonymous gift of $100,000 brought the total up to that amount. It is expected that the new one hundred bed addition to the hospital will be completed by the end of November.

Dr. William J. Pollock has been appointed city physician of Chicago by Mayor Thompson to succeed Dr. Clarence W. Leigh, whose term has expired.

Dr. Frederick E. Strozzi of Buffalo has recently been the recipient of a citation from the King of Italy conferring upon him the grade of cavaliere of the Order of the Crown of Italy for conspicuous services during the late war.

Dr. Homer Dupuy has been elected president of the medical staff of Hotel Dieu, New Orleans, La., to succeed Dr. Marion Souchon.

Gifts to Madame Curie.—According to an announcement by Mrs. William B. Maloney, chairman of the Marie Curie Radium Fund, gifts from American women now total over $162,000. In addition to the gram of radium purchased for $100,000, Madame Curie returned to France with a gram of mesothorium and other costly ores. She received awards from scientific societies amounting to $6,884.51, and a balance of $60.000 remains with the Equitable Trust Company, which is being held by the committee awaiting a decision as to what shall be done with it. There is also being collected a fund of $50,000 for the equipment of Madame Curie's laboratory.

Positions for Medical Internes.—The United States Civil Service Commission announces an open competitive examination for medical interne, to fill vacancies in St. Elizabeth's Hospital, Washington, D. C., and positions requiring similar qualifications. The salary is $1,200 a year and maintenance. Applicants must be graduates of a reputable medical college or senior students in such an institution; they must not have graduated previous to 1915 unless they have been continuously engaged in hospital, laboratory, or research work. Applicants should at once apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C. In the absence of further notice applications for this examination will be received by the Civil Service Commission at Washington, D. C., until the hour of closing business on November 1, 1921.

Obituary Notes.—Dr. ISAAC MORTENSE CORNELL of Wappinger Falls, N. Y., a former resident of Rensselaer, died in Hudson about July 1, at the age of seventy years. He was graduated from New York University in 1877.

Dr. JAMES E. GROFF of Doylestown, Pa., a graduate of Jefferson Medical College in 1880, died on June 11, at the age of sixty-five years. He was the Bucks County representative of the State Department of Health and a former member of the Borough Council.

Dr. LOUIS EDOUARD SCHILLER of Lowell, Mass., a

graduate of Laval University College of Medicine in 1888, died following an operation in a Manchester hospital on June 10, at the age of sixty-three years.

Dr. ORELLO S. MARTIN of Salamanca, N. Y., a graduate of the Cleveland University of Medicine and Surgery in 1870, died on June 6, at the age of seventy-three years.

Dr. DANIEL EDGAR ROBERTS of Keyport, N. J., a graduate of New York University Medical College in 1883, died on June 15, at the age of sixty years.
